Many dogs appear to develop separation problems as the result of forming excessively strong or exclusive bonds with one person. Clarifying the influence of owner attitudes and attachment levels on the development of separation distress is an important area of research. Surprisingly, in this regard, Voith and colleagues (1992) were unable to find a statistically significant relationship between anthropomorphic attitudes or spoiling activities and an increased occurrence of behavior problems. Further, Voith (1994) was unable to show a statistically significant difference between dogs diagnosed with separation anxiety and others not exhibiting the problem, in terms of whether they followed their owners about the house. Of these dogs (N = 100), 36 were diagnosed with separation anxiety, 64 were judged not to be exhibiting separation anxiety, and 3 presented ambiguous signs. Although the general tendency to follow the owner does not appear to be a reliable diagnostic indicator of separation anxiety, many separation-reactive dogs do exhibit pronounced proximity-seeking behavior toward their owners, especially at times immediately preceding owner departures.

Voith's findings question the importance of attachment levels as a predictor or causal factor in the etiology of separation anxiety. The literature on this issue is somewhat conflicted, however. Jagoe and Serpell (1996), for example, detected a significant relationship between sleeping in the owner's bedroom (a proximity measure) and an increased incidence of separation-related elimination problems, but emphasize that their data are inconclusive with respect to determining "whether the behavior problems are the consequences or the cause of the sleeping arrangement" (40). The strongest evidence to date questioning the role of attachment levels as a significant factor in the etiology of separation problems was reported by Goodloe and Borchelt (1998). Among 2018 dogs whose owners responded to a highly detailed questionnaire, the researchers found that measures of attachment, defined as efforts to maintain close proximity to the owner, showed no significant correlation with separation vocalization. They concluded that "panic at separation is not necessarily related to strong attachment. . . . Both humans and dogs can be strongly bonded to other individuals without experiencing anxiety or panic in their absence" (330). Nonetheless, many practitioners still believe that attachment levels play a significant role in the development of separation-related problems.

Although attachment per se may not always be a significant factor in the development of separation-distress problems, the quality of attachment, that is, the degree of dependency (anaclisis) versus secure attachment, may exert a significant influence (Clark and Boyer, 1993). Many separation-reactive dogs do, in fact, exhibit an exaggerated psychological dependency and anxious attachment toward their owners. They may appear insatiable for attention, exhibiting a constant desire for affection or need to maintain close physical contact, appearing uncomfortable unless they are in the owner's immediate proximity. They may engage in pestering antics or barking whenever their owners are distracted from them. Such behavior may occur when the owner diverts his or her attention away from the dog to use the phone. These demanding and persistent attention needs cause some owners to feel very uncomfortable and oppressed by it all. Some separation-anxious dogs will even refuse to eat unless the owner is nearby.

Despite the uncertainty and paucity of data regarding the influence of family size and structure on separation distress, there exists a general impression that separation anxiety presents most often in dogs living with a single owner or a couple. Recently, Topál and colleagues (1998) reported that dogs living in a large family situation tend to exhibit less separation distress when left alone than dogs living in smaller family groups. Perhaps, in larger family groups, with more people coming and going, dogs are exposed to separation in more safe and gradual ways. Also, large families may provide opportunities for multiple attachments to form, thereby preventing the development of an overly exclusive bond forming with one particular person, whose absence elicits separation distress. In regard to a possible connection between social group size and separation anxiety, Podberscek and colleagues (1999) reported that most of the separation anxious dogs in their study (N = 49) lived in homes with two adults and no children. Finally, the Ainsworth's (1972) strange-situation test used by Topál and colleagues provides an interesting nonintrusive means for evaluating some of the current conflicting hypotheses concerning the role of attachment in the development of separation-related distress.

Separation Distress and Retroactive Punishment

Many owners presenting separation-distressed dogs for training believe that their dog's behavior is motivated by spitefulness or resentment at being left alone. In support of these beliefs, such owners may report various signs of guilt in their dog's demeanor, even before they discover the damage or mess made by the dog in their absence. The dog's appearance of *guilt in advance* is sufficient proof for them that the dog "knows" and is acting in a calculated manner (Vollmer, 1977). The first step in the counseling process is to convince them that their dog's behavior is better understood in terms of separation distress (anxiety, frustration, panic, or boredom) rather than vindictiveness. It is of utmost importance to explain in detail how such appearances of guilt probably result from a history of ineffectual punishment and that what they are observing is not guilt at all but rather apparent guilt or pseudoguilt (see *Misuse and Abuse of Punishment* in Volume 1, Chapter 8). It is also useful to point out that retroactive punishment may only worsen a dog's separation anxiety by enhancing its feelings of helplessness and, paradoxically, by increasing its attachment dependency toward the owner.

The owner may have trouble understanding and accepting the notion that dogs cannot causally connect punishment occurring in the presence of a *destroyed item* (e.g., the damaged sofa) with the *act of destroying it,* that is, behavior occurring at some in the past. But even the most resistant owner can be shown the dog's inherent limitations in this regard through thoughtful counseling. One method is to explore some of the differences in the way humans and dogs process, organize, and represent information. Appealing to the human's unique ability to think and symbolically represent experience through concepts and words provides a starting point from which to compare the dog's relative limita-

tions with our own capabilities. It can be explained that humans can conceive of past events in terms of causal relations having deterministic effects on present events, largely as a result of our unique conceptual ability to symbolically represent and relate objects, events, and relations to one another. In addition, it should be emphasized that a dog's appearance of guilt is not an expression of remorse aimed at placating the owner about some past action but rather represents a fearful-submission display aimed at avoiding punishment in situations where it has occurred in the past, regardless of its association with the unwanted target behavior. This theory holds that pseudoguilt is maintained by a triad of conditioned associations involving the following elements (Borchelt and Voith, 1985):

- Evidence of a destroyed object or soiled area.
- The presence of the owner.
- A history of punishment under similar circumstances in the past.

Another scenario involves the possibility that separation distress itself becomes associated with belated punishment as an internal cue. According to this theory, a dog is destructive or eliminates only when it is under the influence of high levels of separation distress; that is, a dog may identify an increased probability of punishment with those occasions when it is particularly upset during separation, coincidentally those same times when destructiveness or elimination is most likely to occur in the owner's absence. This account could help to explain why some dogs appear to show guilt *before* the owner actually finds the evidence of misbehavior. The triad of associative elements in this case includes

- The dog feels distressed.
- The owner returns home.
- The dog has been punished in the past when it felt distressed.

Determining the various causes of pseudoguilt in dogs would provide valuable information. At this point, the debate concerning the causation of pseudoguilt revolves around little more than speculation and educated guesses. Unfortunately, these views have not been experimentally tested. Many anecdotal reports, however, are very supportive of a pseudoguilt interpretation. For example, it is not uncommon for an adult dog that is kept with a puppy during owner absences to exhibit guilt at homecomings, especially on those occasions when the puppy has been destructive or eliminates while the owner is gone.

Aging and Separation-related Problems

A higher incidence of separation problems is observed in older dogs. Chapman and Voith (1990) found that half of 26 older dogs studied (mean age, 12.2 years; and range, 10 to 18 years) were diagnosed with separation anxiety. Milgram and colleagues (1993) studied the degenerative effects of aging on a dog's nervous system and behavior. Older dogs appear to undergo many of the same neurological and behavioral changes that are suffered by elderly people, including evidence of progressive cognitive dysfunction and degenerative brain disorders. In addition to performing basic research, members of Milgram's group have also evaluated the clinical and behavior effects of L-deprenyl (selegiline) on age-related symptoms presented by older dogs (Ruehl et al., 1995). They found that L-deprenyl appeared to enhance cognitive functioning in many of the geriatric dogs treated. As many as 62% of the dog population over 10 years of age may exhibit some sign of cognitive dysfunction (E. W. Kanara, 1998, Pfizer Animal Health Company). Collectively, these various neurological and behavioral changes are referred to as canine cognitive dysfunction syndrome (CCDS). According to K. A. Houpt (AVMA Press Release, 1996), increased susceptibility to separation anxiety and other emotional disturbances in older dogs are related to CCDS and other discomforts associated with aging. She has reported early successes using L-deprenyl in conjunction with behavior modification for the treatment of separation-related problems in older dogs.

Excessive Behavior

Persistence depends on inconsistent treatment of consistent behavior.

ABRAM AMSEL (1971)

PART 1: COMPULSIVE BEHAVIOR

Many compulsive and ritualized habits have been identified in dogs, including compulsive eating (hyperphagia), pica, excessive licking (directed toward the floor, furniture, and hands), rooting at food, digging, mounting, barking, pacing, fence running, and various aberrant aggressive displays. Some affected dogs suffer psychogenic dermatoses, compulsively licking lesions into their limbs and feet [acral lick dermatitis (ALD)]; others monotonously suck on their flanks [a habit most common among Doberman pinschers (Figure 5.1)]; and some appear mesmerized by phantom flies or may lunge and snap at flecks of light on a wall. Dogs taken too early from their mother are prone to develop compulsive, stereotypic habits involving blanket sucking and kneading—a compulsion frequently not appearing until after puberty. Finally, there is a tendency for certain breeds to present compulsive problems more often [e.g., bullterriers and German shepherds (whirling-tail chasing) and Labrador retrievers (ALD)], suggesting a probable genetic factor predisposing some dogs to develop such habits.

DEFINITIONS

Compulsive behavior disorders (CBDs) in domestic animals have received growing attention over the past several years. Some

FIG. 5.1. Flank sucking is a compulsive behavior that is primarily exhibited by Doberman pinschers. (Photo courtesy of V. L. Voith.)

authors have unfortunately borrowed the psychiatric term *obsessive-compulsive disorder* (OCD) in describing the analogous conditions observed in dogs (Luescher et al., 1991; Overall, 1992a–c). This appropriation of terminology is apparently intended to emphasize the close similarity between human OCD and the stereotypic rituals and compulsive repetitive behavior exhibited by domestic animals. Rapoport and Ismond (1996) define *obsessions* in their *DSM-IV Training Guide for Diagnosis of Childhood Disorders* in the following way:

1. Recurrent and persistent thoughts, impulses, or images that are experienced, at some time during the disturbance, as intrusive and inappropriate and that cause marked anxiety or distress.
2. The thoughts, impulses, or images are not simply excessive worries about real-life problems.
3. The person attempts to ignore or suppress such thoughts, impulses, or images, or to neutralize them with some other thought or action.
4. The person recognizes that the obsessional thoughts, impulses, or images are a product of his or her own mind (not imposed from without in thought insertion). (230)

Although dogs may "obsess" like humans suffering with OCD, the possible role of obsession cannot be confirmed by direct report or quantified by any other scientific method currently available. Therefore, to refer to compulsive behavior exhibited by animals as obsessional is both excessively anthropomorphic and possibly misleading. Consequently, the term *compulsive behavior disorder* (Fox, 1963) is used in the following discussion to avoid such confusion.

Stereotypic rituals and compulsive repetitive behaviors are commonly seen in zoo and laboratory animals confined to spaces inadequate for their needs. Such animals can often be observed engaging in various *stereotypies,* including monotonous rhythmic pacing, rocking (chimpanzees), circling, excessive self-grooming, or various nonnutritive consummatory behaviors (e.g., pica). Since compulsive behaviors frequently occur in response to elevated arousal levels, especially as the result of frustration, it has been suggested that such behavior may serve a de-arousal function. In fact, several studies in humans and domestic animals have shown that compulsive repetitive behavior decreases heart rate (Seo et al., 1998). Some compulsive behaviors appear to involve aggressive behavior redirected toward the animal's body, often causing self-injury (Jones and Barraclough, 1978). Frustrative arousal is an establishing operation for aggressive behavior, supporting the notion that self-directed attacks may involve an aggressive motivation.

Compulsive repetitive behaviors are often referred to as stereotypies. Kuo (1967), however, has charged that strictly speaking stereotypic behaviors do not exist:

> No animal responds twice to the same stimulation in exactly the same way. The pacing back and forth of a fox or a wolf in the zoo may appear to the onlooker to be stereotypical. But if one takes quantitative measurements of the pacing movements of the animal one will find that no two pacing movements cover the same ground, involve the same neuromusculature, consume the same amount of energy, and have the identical implicit gradients [that is, internal motivational organization]. (100)

It is important, therefore, to declare at the outset that when the term *stereotypy* is used here, it is employed in a less formal sense than suggested by Kuo and denotes a high degree of regularity, repetitiousness, and inflexibility.

The term *stereotypy* refers to a relatively invariant pattern of compulsive behavior, usually occurring under unnatural conditions, involving varying degrees of distress (e.g., conflict and frustration). *Stereotypies* usually consist of ordinary behaviors (e.g., appetitive, self-grooming, and locomotor activities) that occur out of context, in excess, or in an exaggerated form. The specific elements making up the *stereotypic* ritual consist of repetitive compulsive behaviors that intrude and interfere with normal activities or cause physical injury to the animal (e.g., automutilation). Finally, stereotypies have species-typical relevance and present similar forms in animals belonging to the same species. For example, crib biting (cribbing) is a common stereotypy observed among distressed horses. Affected animals engage in persistent and compulsive biting on wooden stalls and fence posts while simultaneously sucking in air. Dogs do not exhibit cribbing, but instead may lick sores into their carpus or mutilate their tail as the result of chasing it. Although stereotypies may serve a similar function in both species, the stereotypic forms expressed by the two species are different.

Etiology

The etiology of compulsive behavior in dogs is not fully understood; however, several prominent risk factors have been identified. Compulsive behaviors are most frequently reported in dogs that have been stressed by excessive confinement, exposed to sensory-motor deprivation (e.g., boredom and inadequate exercise), provided inadequate social attention and stimulation, or exposed to a conflict-dense environment. Stereotypic behavior patterns may develop as the result of neurobiological stressors; for example, hyperkinetic dogs under the influence of long-term amphetamine treatment may exhibit chomping behavior or spontaneous barking. Also, compulsive symptoms often appear in highly excitable or nervous dogs where no identifiable external precipitating causes or stressors can be identified, suggesting that a genetic predisposition may underlie the etiology of some compulsive behavior disorders. Once established, the frequency and range of contexts under which compulsive behavior occurs may increase and widen over time, making early diagnosis and treatment imperative (Hewson and Luescher, 1996).

Environmental Deprivation and Distress

Dogs may exhibit compulsive behavior when overly confined or deprived of adequate exercise, social contact, or sensory stimulation. Melzack and Scott (1957) reported the case of several 9-month-old Scottish terriers that had been exposed to 7 months of almost total sensory and social isolation (initiated at 4 weeks and terminated at 8 months of age). The dogs exposed to restricted rearing conditions exhibited a variety of motor deficits, increased excitability, and disorganized "wild, aimless" behavior. They also exhibited sharp differences in comparison to normally reared controls in terms of avoidance learning. When tested for nociceptive responsiveness, isolated dogs repeatedly approached the flame of a match even though they were burned by it again and again. Long-term restriction and social isolation have been implicated in the development of compulsive whirling and circling behavior by dogs (Fisher, 1955). Thompson and coworkers (1956) found that, among 11 Scottish terriers reared under restricted conditions, 8 developed the habit of whirling, together with intense vocalization, tail biting, and snarling—all lasting for up to 10 minutes at a time. Some breeds appear to be predisposed to develop the whirling compulsion. The English bullterrier, for example, is particularly prone to develop a serious whirling disorder with automutilation (Dodman et al., 1993; Blackshaw et al., 1994). Also, Hewson and Luescher (1996) note that German shepherds present relatively more often with the habit, but tail chasing and tail biting occur in a variety of breeds (Figure 5.2).

Vacuum Behavior

How is such behavior to be interpreted? Early ethologists proposed that such behavior might be viewed as a form of *vacuum behavior*. Vacuum behavior occurs under conditions of close confinement in which various drive pressures (including aggression) may gradually

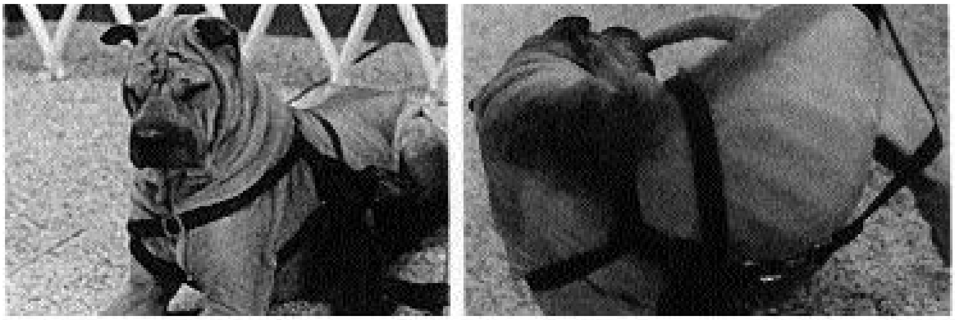

FIG. 5.2. This shar-pei appears to have difficulty staying awake, a sign that may reflect an underlying conflict or fear condition (Voith and Borchelt, 1996). When aroused, the dog turns and bites its tail. (Photos courtesy of V. L. Voith.)

build up and be triggered by objects and stimuli other than normal ones. Such behavior occurs especially in situations where normal outlets and opportunities for appropriate drive-reducing activity are not present. Vacuum behavior appears to spontaneously erupt out of frustrated internal drive tensions unable to find adequate expression otherwise. When vacuum behaviors are motivated by aggression, they frequently take the form of whirling topographies, with the aggression being directed at the animal's body (Lorenz, 1981). Whirling in dogs, therefore, may not be an entirely neutral motoric compulsion but an aggressive vacuum behavior directed at the animal's own body. This interpretation is consistent with the description of whirling given by Thompson et al. (1956) and others:

> Whirling can be described as follows: very rapid, jerky running in a tight circle; shrill, agonized yelping; barking and snarling; and tail snapping and tail biting. The syndrome may last from 1 to 10 minutes. It is usually heralded by certain characteristic signs. The dog suddenly becomes motionless, cocking its head up and back, as if looking at its own tail. It begins to growl viciously, and its eyes take on a glazed expression. These signs may continue for a minute or two, increasing in intensity until the full-blown fit occurs. (939)

Swedo (1989) proposes that compulsive behavior may be the result of a dysfunctional releaser and fixed-action pattern (FAP):

> Obsessive-compulsive rituals can be viewed as inappropriately released fixed-action patterns. Our work with more than 200 children and adults has led us increasingly to view OCD in this fashion. For example, obsessive patients, who check and recheck that the coffee pot is unplugged, all seem to perform each checking pattern in an identical fashion. Their behavior is perfect in form, but after the first check, it is ineffectual and inappropriate. To follow an ethological model, one must of course, ask: what is the releasing stimulus in OCD? Is it internal (e.g., chemical) or external (e.g., environmental stress)? How does it effect the release of the ritualized fixed-action pattern? (273)

Given the relatively narrow range and specificity of compulsive behavior disorders, it makes sense to interpret them in terms of species-typical adaptations to persistent frustration or conflict. Under the stressful influence of adverse frustration or conflict, a *releaser* mechanism may become defective, causing predisposed dogs to inappropriately repeat the same rigid and perseverating loop of behaviors. Pathological compulsive behavior appears to operate independently of voluntary control and normal expectations. Like *instinctive* behavior, compulsive habits become progressively ritualized, stereotypic, and automatic—features consistent with an FAP interpretation.

Normal versus Abnormal Compulsions

Under extreme and adverse environmental conditions, it is reasonable to ponder whether such behavior is truly aberrant or simply an adaptive response to an aberrant environment, Mugford (1984) writes regarding this diagnostic dilemma concerning whirling behavior:

> A heterogeneous species such as the dog, raised in a multitude of environments and social situations, presents even greater variability [than a laboratory mouse]. Thus, one generalizes about the behaviour of cats and dogs at one's peril, and the greater one's knowledge of the two species, the less appropriate seems the term "abnormal." For instance, "whirling" is a commonly occurring stereotype in kenneled dogs, but is unusual in free-roaming or home situations. If one examines the behavioural options available to a kenneled dog, one finds that restricted movement and reduced social contacts have made whirling a highly appropriate behaviour in this environment. It brings vestibular stimulation and attention from kennel staff, and in that setting is certainly not an abnormal behaviour. (134)

According to Fox (1974), many compulsive compensatory behaviors may be aimed at resolving internal conflict or other states of anxious arousal:

> If the environment does not provide varied stimulation, the subject may compensate by creating its own varied input by elaborating stereotyped motor acts or by directing specific activities toward inappropriate objects (such as copulating with its food bowl). The stereotyped motor acts (thumb-sucking, self-clutching, and rocking in primates) developed while in isolation may be performed when the subject is in a novel environment and may serve to reduce arousal or anxiety because they are familiar activities and may be comforting. (72–73)

Hewson and Luescher (1996) argue that most compulsive behaviors can be traced to conflict situations involving a high degree of frustrative arousal. Subsequently, the behavior may be "emancipated" from the original context and be expressed in other situations, when the dog is under the influence of increased excitement or stress. Obviously, drawing a definitive line is difficult when it comes to labels like "normal" and "abnormal."

Displacement Activity

Classical ethologists interpreted and described compulsive repetitive behavior in terms of displacement activity. Displacement activity occurs when some course of action is thwarted (frustration) or when two opposing motivational tendencies are elicited at the same time (conflict). Under the influence of frustration or conflict, a substitute behavior may be emitted, often coming from a remote functional system and possessing little apparent motivational relevance for the conflict at hand. A classic example of such substitutive displacement behavior was observed by Tinbergen (1951/1969) in male sticklebacks. These fish are highly territorial and actively defend their nests from the invasion of conspecifics. However, if two male sticklebacks encounter each other on the boundary line between their respective territories, two antagonistic drives may be simultaneously induced. As a result, equally strong fight and flight drives are activated at the same time, resulting in approach-avoidance conflict. The resulting conflict is resolved when the two fish resort to digging behavior—a functionally remote species-typical displacement activity. While digging, sticklebacks point their heads downward and dig into the sand with their mouths as though making a nest. Interestingly, if male sticklebacks are forced to nest too closely together, "they will show nearly continuous displacement digging and the result is that their territories are littered with pits, or even become one huge pit" (117). According to Lorenz (1981), among animals, displacement activities are common everyday occurrences that are specific to particular conflicts and no others; that is, conflict situations among most animals and birds are highly stereotypic, producing only one displacement activity or "sparking over" action pattern.

Under conditions of behavioral or emotional conflict, requiring that a dog choose between two equally unacceptable courses of action, substitutive behaviors or *displacement activities* may help to restore balance and homeostasis within a behavioral system threatened by invasive anxiety or even (in the case of extreme conflict) functional collapse. Subsequently, the displacement activity may be activated whenever the animal is confronted with a difficult or insoluble conflict, providing a mechanism for safely killing time until a more adequate response can be found to resolve the situation. Since the substitute behavior results in the reduction (if only temporarily) of anxiety and the restoration of equilibrium, it may become highly reinforcing

for animals to perform. This may help to explain why CBDs do not extinguish over time, as in the case of other behaviors occurring in the absence of reinforcement. Perhaps the substitute behavior is repeated again and again because it produces strongly gratifying and self-reinforcing effects.

The substitute response is often a behavioral non sequitur; that is, it does not follow from learned expectancies and predictions about the environment but rather represents a behavioral exception evoked under conditions of stress and conflict. The autonomous nature of the CBD gives it the appearance of being irrational, without purpose or apparent goal, and operating independently of normal constraints and inhibitions. Because the substitute behavior does not conform to the ordinary rules of learning, it may be refractory to modification. The substitute behavior is essentially an autonomous anomaly, presenting under the control of variables outside the scope of normal self-regulatory behavioral mechanisms. As a result of their exceptional character and origin, compulsions may exert a *superstitious* or obsessional fascination, further distinguishing them from ordinary behavior.

In fact, many compulsive behaviors appear to take the form of something like a superstition. Lorenz described in detail the behavior of one of his graylag geese that had developed a complex compulsion, apparently driven by anxiety reduction:

> At first, she always walked past the bottom of the staircase toward a window in the hallway before returning to the steps, which she then ascended to get into the room on the upper floor. Gradually she shortened this detour, but persisted in initially orienting towards the window, without, however, going all the way to it. Instead she turned at a 90 degree angle once she was parallel to the stairs. (Quoted in Swedo, 1989:282)

On one occasion, Lorenz forgot to let the goose in at the accustomed time. It was nearly dark outside, and she had become excited about the opportunity to get inside. As a result, instead of going through her typical ritual, she darted directly toward the stair steps and began to climb:

> Upon this something shattering happened: Arrived at the fifth step, she suddenly stopped, made a long neck, in geese a sign of fear, and spread her wings as for flight. Then she uttered a warning cry and very nearly took off. Now she hesitated a moment, turned around, ran hurriedly down the five steps and set forth resolutely, like someone on a very important mission, on her original path to the window and back. This time she mounted the steps according to her former custom from the left side. On the fifth step she stopped again, looked around, shook herself and performed a greeting display behavior regularly seen in graylags when anxious tension has given place to relief. I hardly believed my eyes. To me there is no doubt about the interpretation of this occurrence. The habit had become a custom which the goose could not break without being stricken by fear. (Quoted in Swedo, 1989:282)

This interesting anecdote is relevant to the way in which some common compulsive habits appear to develop in dogs.

Many ritualized habits develop around entryways and boundaries, often becoming extremely energetic and bizarre. For example, a common compulsion among dogs confined outdoors is fence running and fighting (see *Sources of Territorial Agitation: Fences and Chains* in Chapter 7). Sometimes, aggressive behavior is very dramatically increased under such conditions of confinement. Dogs with dog-fighting problems or exhibiting aggression toward strangers often exhibit intensely exaggerated displays while restrained on a leash or chain. In many cases, the aggressive behavior may seem vicious and virtually uncontrollable. Surprisingly, however, if such a dog happens to escape its owner's hold or confinement, the aggressive efforts may almost instantly fizzle out. On recognition that it is free, the previously uncontrollable dog may appear disoriented and confused about its intentions. This is definitely not always the case, though, with many dogs known to deliver particularly savage attacks after breaking free of a chain or slipping a leash. In general, any situation in which a dog is highly motivated to behave in some particular way but prevented from doing so by physical restraint or threat of punishment may increase the likelihood of compulsive behavior.

Adjunctive Behavior and Compulsions

Schedule-induced Excessive Behavior

Many experiments have been performed using intermittent reinforcement and observing confluent effects on behavior, especially exaggerations in drinking, pica, hyperactivity, and aggression (Falk and Kupfer, 1998). In the classic experiments performed by John Falk (1961), rats were trained to lever press on a variable schedule of reinforcement. A small pellet of food was presented on a variable-interval 1-minute schedule (i.e., the rats received reinforcement averaging 1 pellet per minute), so long as they lever pressed at least once between reinforcement opportunities. In addition, the rats were given free access to water. Falk noticed that the rats habitually drank after obtaining reinforcement, usually consuming around 0.5 ml before continuing to lever press. The cumulative result was the consumption of an extraordinary amount of water over the course of a typical 3-hour session. On average, rats drank 90 ml of water, a significant excess of consumption over the normal intake of 27 ml of water consumed by an average rat daily. In other words, the rats drank approximately 50% of their body weight in water during each training session. This phenomenon is referred to as *schedule-induced polydipsia.*

Additional experiments demonstrated that an important factor in the development of schedule-induced polydipsia is the duration of time between reinforcing events. Schedule-induced polydipsia is *time dependent,* with 2- to 3-minute intervals producing the largest magnitude of polydipsia. Shorter or longer intertrial intervals produce less polydipsia or result in normal water consumption. These findings suggest that the phenomenon is controlled by a *bitonic function:* "sessions with either short or long intervals between pellet consumption produce normal amounts of drinking, while intermediate values induce polydipsia" (Falk, 1981:317). Another important variable associated with the phenomenon is deprivation. Rats in Falk's studies were reduced to 80% of their free-feeding body weight. Rats of normal weight are significantly less affected by schedule-induced polydipsia, suggesting that *hunger tension* may influence the phenomenon.

Other forms of adjunctive behavior, including aggression and hyperactivity, have been associated with intermittent reinforcement. For example, a pigeon working on an intermittent schedule of reinforcement may turn and attack a nearby conspecific when the reinforcer is delivered. Although such frustration-related aggression is not uncommon, the magnitude of adjunctive attacks goes far beyond what is normally observed to occur under frustrative conditions (Campagnoni et al., 1986). Similar results have been observed in squirrel monkeys who were maintained on a variable-interval schedule. After receiving reinforcement, the monkey would aggressively grab and bite a rubber hose provided to receive such attacks. Increased activity has also been observed to occur as the result of intermittent reinforcement. For example, wheel running was significantly increased when rats were trained to work under a variable-interval 1-minute schedule of reinforcement.

Food is not the only reinforcer capable of generating schedule-induced excessive behavior. If a well-fed and watered rat is given intermittent access to an activity wheel, several adjunctive behaviors like rearing, licking, and position changes undergo an increase of emission. Studies of people under the influence of variable interval schedules have also shown increases in general activity levels, eating and drinking, and grooming activities. Finally, pica has been observed in animals stressed on brief-interval schedules, suggesting a possible role of schedule-induced motivations underlying the development of such behavior problems in dogs.

Schedule-induced Escape

An average pigeon is willing to work only so long as the schedule of reinforcement stays within certain limits. Rather than work on an exceedingly lean schedule of reinforcement, most animals will opt to press a second key wired to turn off (self-signaled time-out) the reinforcement contingency, even though the action postpones a possible opportunity for

eventual reinforcement. This phenomenon is referred to as *schedule-induced escape.* Paradoxically, pigeons under the influence of food deprivation and weight loss tended to produce the most self-induced time-outs. This is counterintuitive to what one would expect from animals suffering from the effects of deprivation and hunger. An interesting example of schedule-induced escape behavior in dogs was reported by Luescher (1993b). The case involved a 2½-year-old German shepherd that, as a working police dog at an airport, searched planes for explosives. The dog was an enthusiastic and effective detector dog that routinely worked continuously for 1½-hour stretches. However, over the course of a year, his stamina and willingness to perform deteriorated until he was unable to work for periods exceeding 15 minutes at a time. After 15 minutes, he abruptly quit, appeared exhausted, and stood motionless looking at his handler. In addition, the dog developed over the same period a persistent collateral habit of whirling while in the police vehicle (perhaps a compulsion resulting from anticipatory conflict) and had become progressively aggressive toward pedestrians approaching it. The usual search of the plane took approximately 2½ hours, during which time the dog was provided one "successful" find of a dummy bomb, resulting in praise and tug with a toy. Luescher speculates that the schedule of intermittent reinforcement utilized was too lean; that is, the dog was required to search too long for a single reinforcement. He implicates the phenomenon of adjunctive escape as a possible explanation for the dog's behavior. The dog, rather than endure the aversive intermittent schedule, simply quit, even though it meant losing access to the eventual reinforcer:

> Although indicating was reinforced each time in the dog of this report, searching was reinforced as seldom as once in 2.5 hours. Hundreds of sniffing responses may have been performed over a period of up to 2.5 hours, before searching was reinforced by the smell of explosives. Thus, the ratio of nonreinforced to reinforced correct responses was large, and the dog would be assumed to perceive its work as increasingly stressful. . . Because the ride to the airport always preceded the work there, the dog became classically conditioned to associate the ride in the truck with the stressful situation at the airport. The ride thus became a conditioned stimulus, in response to which the dog exhibited increased anxiety. (1539)

Displacement Activities and Compulsions

Falk (1977, 1981) views adjunctive behavior as natural response to equivocal circumstances in which decisive action is not possible. Such behavior may serve an important adaptive function by stabilizing conflict situations involving opposing motivational constraints. He argues that adjunctive behavior is commonly observed in nature when opposing motivational vectors are in equilibrium and *maximally equivocal* (Figure 5.3). These opposing motivations frequently involve defense of territory, feeding, sexual privileges, maternal protection of young, and self-preservation set against the possible need to withdrawal or flee from the situation:

> In terms of evolutionary processes, the adaptive function of adjunctive behavior is to delay commitment to either engaging a situation or escaping from it until one or the other vector becomes clearly ascendent. (Falk and Kupfer, 1998:341)

Among humans, various public rituals typically form around these important transitional cultural and social events (Falk, 1986). When opposing motivations are in approximate equilibrium, action is made uncertain. Under such circumstances, adjunctive behavior or displacement activity emerges in order to temporarily postpone decisive action, thereby preventing a potentially costly mistake. According to this theory, displacement activities stabilize the situation long enough for one of the opposing components to become ascendant and result in a stable resolution:

> The processes that produce displacement activities are precisely those responsible for adjunctive behavior. In both cases, an important activity is in progress or a crucial commodity is being acquired. These are usually territorial defense, courtship and mating sequences, and parental behavior in ethologic studies; scheduled access to food, water, activity, or money in investigations of adjunctive behavior. In one

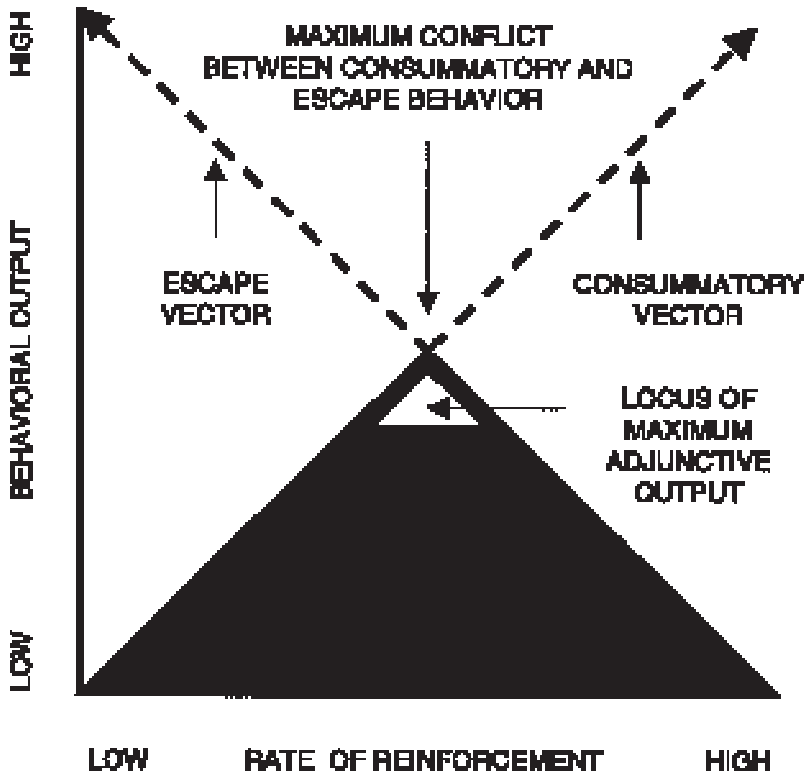

FIG. 5.3. Maximum adjunctive output occurs at the point of highest potential conflict between consummatory and escape vectors. After Falk (1981).

> case the ongoing behavior is impeded by situational interruptions (intruders, inadequate releasing stimuli); in the other, by schedule constraints allowing only episodic access. The resulting behavior is described as incongruous or irrelevant in ethnologic observations and as persistent and excessive in adjunctive behavior investigations. I suggested that displacement activities have evolved because they serve an adaptive function: allowing stabilization of an unclear situation, with a nonprecipitous resolution of competing vectors. . . . Adjunctive behavior, like displacement activities, is behavior that probably serves to block premature escape from nonoptimal situations. For example, a feeding environment providing a marginal amount of food induces a variety of adjunctive activities. In a natural environment, such behavior might function to delay abandonment of a feeding range or patch that, while marginal, is nevertheless adequate. (Falk, 1981:328–329)

There are several obvious implications of Falk's research for the understanding of compulsive behavior. In cases where biologically significant behavior is impeded by environmental constraints evoking opposing motivations of nearly equal strength, one would expect to observe the appearance of exaggerated adjunctive behavior. Adjunctive behavior functions to delay unnecessary retreat from anxious or frustrative arousal, perhaps allowing time for one or the other opposing motivational vectors to assume a definitively dominant influence over the conflict situation. Persistent and excessive adjunctive behavior (compulsive perseveration) results when neither side of a conflict assumes an ascendant role.

Schedule-induced paw grooming (licking) by rats has potential significance for understanding compulsive licking (ALD) in dogs. Lawler and Cohen (1992) observed that some

rats operating under a fixed-time schedule of reinforcement (food was delivered every 2 minutes regardless of an animal's behavior) developed a habit of paw licking. The adjunctive grooming ritual occurred shortly after food was presented and lasted for approximately 30 seconds thereafter. Ordinarily, in rats, paw grooming is a brief initiating segment of a more elaborate grooming activity that includes nose wipes, ear wipes, and overall body grooming. In the case of persistent adjunctive paw grooming, there appears to be a stress-modulating function being performed under the condition of intermittent reinforcement. In the case of canine ALD, the initial increase in self-licking may begin as the result of a similar adjunctive or stress mechanism and then gradually come under the control of various other mechanisms (e.g., the endogenous opioid system), perhaps providing a source of intrinsic reinforcement maintaining the habit.

Conflict and Coactive Factors

Compulsive behavior appears to be most commonly associated with situations where opposing motivational vectors (establishing operations) converge and require that the dog take one of two equally unacceptable courses of action. Given this definition of conflict, dogs are exposed to many conflictual situations in the course of their lives, but relatively few of them go on to develop compulsive habits that require professional intervention. In fact, most dogs appear to adjust to the adversity of conflict and frustration without developing any problems at all. Currently, it is not clear how compulsive disorders develop, but most behavioral theories incorporate some mix of influences, including adverse anxiety, frustration, learned helplessness, boredom, and attention seeking.

Anxiety and Frustration

Many compulsive behavior disorders appear to present under the influence of excessive frustrative arousal and stress (Hewson and Luescher, 1996). Anxiety, frustration, and other forms of stressful arousal have been frequently implicated in the development of CBDs. These adverse emotional antecedents are frequently the result of conflict situations. Disruptive conflict, sufficient to disrupt purposive behavior, predictably occurs under circumstances in which dogs are strongly and equally motivated to behave in mutually incompatible ways at the same time. Presumably, under the influence of disruptive conflict, susceptible dogs are caught up in a psychologically intolerable state in which they are compelled to act but are unable to do so in a decisive way—a situation that cannot be merely escaped or ignored. Under such circumstances, a remote substitute behavior, irrelevant to both horns of the conflict, may be emitted and repeated as long as the conflict continues without resolution. This general theory has considerable appeal and is frequently referred to in the literature; however, it should be emphasized that the origin of many common compulsive behaviors cannot be readily traced to an identifiable precipitating conflict. In addition to conflict, many other environmental conditions may cause receptive dogs to exhibit compulsive behavior. Although the conflict theory may not explain the development of all compulsive behaviors, compulsions and other maladaptive behaviors have been produced and studied under laboratory conditions by inducing insolvable conflict.

Since the time of Shenger-Krestovnikova's famous experiments inducing neurosis in dogs (Pavlov, 1928/1967), many related experimental animal models have been used to investigate the etiology of neurotic behavior (see *Learning and Behavioral Disturbances* in Volume 1, Chapter 9). Several of these studies have stressed the importance of insolvable conflict in the development of neurotic compulsions. For example, Maier (1961) succeeded in producing a rigid behavioral fixation or stereotypy in rats by exposing them to an insolvable discrimination task. The rats in his experiment were unable to solve the "rigged" discrimination successfully and soon refused to jump, since doing so resulted in their bumping into locked discrimination cards and falling into a safety net below. The decision not to jump, however, was not a permanent solution, since the experimenter soon prodded them into action with a blast of air.

The result was the development of a position stereotypy or fixation. The rats chose one side or the other and persistently jumped in that direction even after the discrimination task had been restored to a solvable form. Maier speculated that the persistence of these abnormal behavioral fixations paralleled neurotic compulsive habits in human subjects.

A central feature of Maier's method for inducing neurosis is the imposition of a high degree of tension caused by avoidance-avoidance conflict. Such conflict is generated by placing an animal in an impasse between two equally undesirable alternatives. Avoidance-avoidance conflict is commonly observed in punitive situations where a dog is unable to abstain from some behavior or unwilling to perform a required behavior, but, nonetheless, is imposed upon to abstain or perform by threat of punishment. If this conflict situation is accompanied by the presence of poorly differentiated discriminative stimuli, then one is presented with a very similar scenario to the one described by Maier.

Another common configuration of conflict involves the evocation and collision of incompatible unconditioned responses, usually in the form of simultaneous approach and withdrawal behavior. The result is an approach-avoidance conflict. This form of conflict was studied by Masserman in his experiments with cats. Cats that were previously trained to expect food on approach to a hopper were exposed to an startling blast of air or shock as they began to eat. The unexpected aversive stimulation triggered a disorganizing expectancy reversal, causing the cats to exhibit a persistent pattern of phobic and compulsive behavior.

Workers in Pavlov's laboratory used a similar method to induce neurotic symptoms (Pavlov, 1928/1967, 1941). First, dogs were conditioned to expect the presentation of food following a certain number of metronome beats. Once the conditioned response was well established, an aversive stimulus was arbitrarily presented instead of the expected food. The approach-avoidance conflict generated by this expectancy reversal resulted in disturbances that Pavlov called *focal neuroses* or displacement stereotypies. Another procedure used in Pavlov's laboratory involved simultaneously eliciting potent incompatible emotional reactions (e.g., presenting food to a hungry dog together with shock). This arrangement caused a violent collision of incompatible expectations, precipitating internal approach-avoidance conflict and associated neurotic symptoms. Pavlov believed that approach-avoidance conflict was etiologically relevant to the development of OCDs in humans (Astrup, 1965). The disturbing effects of conflict led Pavlov (1941) to imagine what dogs might say, if they were able, about the causes of their various "neurotic" disturbances:

> One can conceive in all likelihood that, if these dogs which became ill could look back and tell what they had experienced on that occasion, they would not add a single thing to that which one would conjecture about their condition. All would declare that on every one of the occasions mentioned they were put through a difficult test, a hard situation. Some would report that they felt frequently unable to refrain from doing that which was forbidden and then they felt punished for doing it in one way or another, while others would say that they were totally, or just passively, unable to do what they usually had to do. (84)

Pavlov's observations emphasize that some dogs, especially overly excitable or inhibited ones, may respond adversely to aversive compulsion. Overly excitable dogs are less able to control impulses without extreme exertion and strain, whereas overly inhibited dogs may be unable to respond effectively under the pressure of punitive compulsion. Pavlov's observations also underscore the importance of providing dogs with adequate instrumental control over punitive events. When punishment occurs in an unpredictable or uncontrollable manner (i.e., independently of what a dog does or does not do), it may exert excessive or, potentially, pathological demands upon a dog's ability to adjust.

Negative Cognitive Set

Although conflict and stress appear to represent significant necessary conditions for the expression of compulsive behavior, as already noted, conflict alone does not provide an adequate explanation for the appearance of

CBDs. Identical exposure to conflict and stress may cause some dogs to develop a compulsive behavior problem, while leaving other dogs unaffected. A dog's ability to respond adaptively (or not) to conflict and stress is determined by various biological factors, the overall quality and cumulative effects of previous learning, and the animal's general ability to cope under adverse conditions. All three factors affect the manner in which dogs respond to conflict and stress. Dogs susceptible to CBDs may be more prone to exhibit compulsive behavior because they are unable to perform efficiently under stressful pressure. The cause of this impairment may be traced to an acquired cognitive deficit (see *Learned Helplessness* in Volume 1, Chapter 9). Some dogs exhibiting compulsive behavior may be affected by a pervasive belief or *negative cognitive set,* such that whatever they choose to do will be equally ineffectual and irrelevant to what actually occurs as a result of their action. The influence of a such an inimical efficacy expectancy may intrude most disruptively in emotionally stressful situations where a choice must be made between two highly emotional and opposing alternatives. As the result of a history of excessively unpredictable and uncontrollable learning events, vulnerable dogs may be predisposed to respond to stressful situations in more arbitrary and rigid ways. Under the stress of conflict, such dogs may be affected by a global pessimism or *learned helplessness,* inclining them to expect that all possible responses available to them will be equally useless and ineffectual. When exposed to heightened stress and conflict, predisposed dogs (unable to act functionally and voluntarily) may be compelled to adopt compulsive behavior as a stress-reducing strategy.

Boredom

Another factor putatively implicated in the development of compulsive behavior in animals is boredom (see *Boredom* in Chapter 4). Except in extreme cases of social isolation or excessive confinement, appealing to boredom as a primary cause of compulsive behavior is difficult to defend. Many dogs are exposed daily to incalculable boredom, but few of them develop compulsive habits. Boredom is common, but compulsive disorders are relatively rare. Further, if boredom were a primary cause of compulsive behavior, one would expect that supplemental activities, exercise, and social contact should reverse or attenuate observed symptoms. Although environmental enhancements aimed at optimizing stimulation for dogs may be helpful, once compulsive habits have formed the provision of environmental enrichment alone is rarely sufficient to modify the behavior.

Attention Seeking

Compulsive habits may be reinforced by social attention (both negative and positive) obtained by a dog from either its owner or other persons with whom it comes into regular contact. Many whirlers and tail chasers can be prompted to perform the behavior by waving a finger around above their heads. While the stimulus itself may elicit an unconditioned whirling response in some dogs, such behavior may have been learned as a result of deliberate or inadvertent training. Some rather bizarre habits have been identified as operating under the influence of attention-seeking motivations. Hart (1980), for example, has reported an *attention-getting* motivation underlying a wide array of compulsive behaviors and psychosomatic conditions:

> Attention-getting behavior almost defies categorization. The behavior may appear as a major disorder such as lameness, paralysis of the rear legs, shadow chasing or hunting for imaginary objects. The behavior may involve autonomic response such as diarrhea, vomiting or asthmalike reactions. Mutilation of a leg or tail, or seizurelike disorders, may also be attention-getting. (99)

Unfortunately, the way attention-seeking behavior is usually interpreted involves considerable anthropomorphic contamination, and the concept needs a scientific definition. In general, the significance of attention seeking is probably related to active-submission behavior, rather than a calculated effort by the dog to obtain enhanced social contact and recognition. The presence of affection and fear underlying active-submission behavior together with social frustration provides a potential locus of significant conflict, perhaps

sufficient to support compulsive behavior (see *Adjunctive Generation of Hyperactivity,* below). Chronic conflict between the owner and dog involving affection and fear offers an alternative interpretation of attention-seeking behavior based on an adjunctive generator analysis—an approach that may be more useful than the usual social reinforcement theory. Active-submission behavior and associated excesses (e.g., jumping up, vocalizing, pawing, licking, and various other active-approach and contact excesses) are often the objects of considerable control efforts—efforts that aim to thwart or suppress their expression. Thwarting active-submission behaviors may simultaneously increase social conflict as well as introduce significant frustration, thereby possibly facilitating compulsive behavior in susceptible dogs.

The adjunctive conflict analysis offers an alternative way to understand how such diverse problems as those identified by Hart could operate under the influence of an *attention-getting* motivation. Figure 5.4 shows a Border collie that presented with a compulsion to retreat under a desk whenever the owner picked up the telephone. Once there, the dog shadow chases, barks, and snaps at nonexistent objects. Although clearly suggesting an attention-seeking etiology (the behavior occurs primarily in the presence of one family member), oddly the owner expressed concern about the dog's lack of affectionate display and closeness. In addition, the dog is highly reactive, fearful of novelty, and intolerant of unfamiliar social situations. Besides the aforementioned compulsions, the dog exhibits several other variants that regularly occur under the influence of a variety of social triggers. Apparently, such behavior is emitted in the presence of adverse or stressful circumstances as a coping or holding pattern. The Border collie's compulsive behavior is probably due to a genetic susceptibility, fostered and incubated under the influence of active-submission conflicts and persistent frustration resulting from its failure to achieve more satisfying social relations.

FIG. 5.4. This Border collie exhibits a variety of compulsive habits, especially lunging and snapping at shadows and at her reflections. Episodes are reliably elicited whenever the owner talks on the phone, at which time the dog runs under a desk and yelps, whines, barks, and lunges at shadows.

COMPULSIVE BEHAVIOR PROBLEMS

Licking, Sucking, and Kneading

A common compulsive habit observed in dogs is sucking and kneading of blankets. This behavior is highly correlated with removing a puppy from the mother too early in its development. In many cases, the sucking-and-kneading compulsion does not appear until after puppies reach puberty, sometimes not until after 1 year of age. Dogs exhibiting this habit rhythmically suck and knead on a blanket as though quietly nursing on it. Owners note that it most often occurs when dogs appear slightly stressed by environmental events or are bored. In most cases, the habit is not self-injurious and is left untreated, partly because it gives such dogs so much apparent pleasure. The habit is best controlled through prevention. Puppies taken from the mother prior to normal weaning times should be fed by a method as similar to natural nursing activity as possible. Levy (1941) suggests that the sucking compulsion may be driven by frustration. He carried out an experiment in which puppies were given adequate milk to satisfy their nutritional needs but not enough time feeding to satisfy their sucking needs.

The control puppies, on the other hand, were given adequate milk to satisfy their hunger, as well as time to satisfy their sucking needs. In contrast to the satisfied group, the frustrated puppies exhibited increased sucking activity directed at nonnutritive objects (e.g., other puppies, their paws, and a variety of objects). In addition, as they matured, frustrated puppies engaged in excessive licking of their food plates.

Other compulsive oral habits commonly exhibited by dogs involve excessive licking directed toward the body, people, floor, or furniture. When dogs direct licking toward their extremities (usually the carpus or tarsus), this may cause physical effects ranging from minor alopecia (hair loss) and hyperplasia (thickening of the skin) to lick granulomas (Figure 5.5). Such problems usually involve both medical and behavioral causes and should be treated jointly by a veterinarian and a behavior counselor. Excessive self-directed licking is especially common among large breeds (e.g., Labrador retrievers, golden retrievers, and Doberman pinschers). Licking directed toward furniture or flooring is usually less problematic, but occasionally dogs lick so much that they inflict minor abrasions and injuries to the lower jaw or lips.

FIG. 5.5. This German shepherd exhibits a classic carpal granuloma resulting from compulsive licking.

Petra Mertens (1999) describes an unusual case involving a male 4-year-old miniature bullterrier. The dog, which the female owner characterized as being very oral and excessively interested in food, had developed a persistent habit of licking the arms and legs of her quadriplegic husband. One afternoon, the owner left the dog alone with her husband to find upon returning that the dog had erstwhile chewed off her husband's first toe and removed half of the second one. This rare example of allomutilation (from the Greek *allos* or "other") appears causally related to the dog's persistent tendency to lick the husband's skin, gradually resulting in gnawing, and, finding no inhibitory feedback limiting the extent of the oral behavior and its damage, resulted in the loss of the man's toes. This event underscores the importance of exercising caution when exposing persons who lack nociceptive sensitivity in their extremities to dogs with heightened oral interests. Dogs exposed to such individuals should be carefully supervised and receive inhibitory training to limit excessive licking behavior.

A key consideration in the treatment of compulsive behavior problems is the identification of social and environmental sources of stress and conflict. Excessive self-licking has been associated with socially conflicted situations, such as the introduction of a new animal (or person) into the household or separation-related distress. For some dogs, grooming and licking may be a way to cope with anxiety. Some compulsive licking habits appear to be under the influence of an attention- or comfort-seeking motivation. In such cases, licking may have been initially triggered by an actual traumatic event or injury, but, as the result of owner attention giving and comforting while licking, the licking behavior may have subsequently become a means to obtain attention from the owner. Finally, excessive crate confinement or neglect has been implicated in the development of grooming and licking excesses. For example, Hetts and colleagues found that isolated dogs tend to engage in more "bizzare

movements" and distress vocalizations, and when confined to small cages they tend to exhibit more grooming activities (e.g., scratching, licking, and biting the skin). Finally, excessive licking is often associated with etiological factors other than psychogenic ones, including allergies, previous trauma, foreign bodies, infection, and arthritis (Veith, 1986). Such self-injurious licking habits often respond to medical treatment alone. Severe and refractory cases are sometimes treated with radiation therapy (Rivers et al., 1993). Once well established, ALD is rarely completely curable but is manageable through a variety of veterinary and behavioral interventions. In cases where psychogenic factors are also suspected to play a contributory role, systematic behavioral efforts should be introduced to prevent symptoms from reoccurring.

Locomotor Behavior

Many examples of locomotor compulsive behavior have been already discussed. The most common movement compulsions and stereotypies involve repetitive pacing, running fence lines, and other locomotor excesses. Under close confinement, dogs may develop persistent whirling habits. Other dogs may spend large amounts of time and energy unproductively pacing or charging up and down fence lines in a stereotypic manner or exhibit compulsions such as leaping up and down. Obviously, such dogs are motivated to move beyond the fence by the attraction of some external stimulation or desire to roam. The fence represents a conflict-laden barrier between what a dog would prefer to do and what it is constrained to do as the result of the surrounding fence, underscoring the role of frustration in the development of such problems. A compulsive factor appears to affect territorial aggression and fighting behavior occurring along fence lines (see *Variables Influencing Territorial Aggression* in Chapter 7). Similar conflict-generating conditions occur when dogs are restrained on leash. In this latter case, the dog is attracted by various impinging stimuli but prevented from acting on its impulses by the confinement of the leash. The result is compulsive investigatory and pulling behavior in spite of the discomfort produced by the owner's frustrated yanking back. Dogs chained outdoors may develop compulsive digging or chewing habits, providing a substitute outlet for the frustration caused by such restraint. R. C. Hubrecht and colleagues (1992) found that dogs housed in small pens tend to develop stereotypic circling habits, behavior that is probably expressed as pacing when dogs are housed in larger pens. Finally, some forms of hyperactivity may be attributable to a compulsive etiology (see below).

Sympathy Lameness: Deceit or Compulsion?

When exposed to increased anxious arousal, dogs that have suffered injury to a limb or foot may display a pattern of limping or paw raising in the absence of actual injury or pain (Fox, 1962). The result is a compulsive reliance on the display of lameness in order to obtain *reward-sympathy* from the owner whenever the dog becomes distressed or anxious. Under conditions of emotional conflict, dogs may draw attention to themselves and gain relief by exhibiting *sympathy lameness.* To my knowledge, the first recorded case of sympathy lameness was reported by George Romanes (1888) in his interesting book *Animal Intelligence.* Romanes recounts the observations of a correspondent who had written to him about a peculiar behavior that gave credence (in his opinion) to the possibility that dogs can exhibit deceitfulness:

> He [a King Charles spaniel] showed the same deliberated design of deceiving on other occasions. Having hurt his foot he became lame for a time, during which he received more pity and attention than usual. For months after he had recovered, whenever he was harshly spoken to, he commenced hobbling about the room as if lame and suffering pain from his foot. He only gave up the practice when he gradually perceived that it was unsuccessful. (444)

Lorenz (1955) describes a similar case that he labeled a behavioral "swindle" (suggesting a similar interpretation to the one proposed by Romanes) involving feigned lameness exhibited by one of his dogs. The dog in question had suffered a severe strain with tendonitis

that, consequently, required special attention and extended care. The dog recovered but apparently learned that limping produced sympathetic treatment from her owner. She subsequently developed a selective lameness whenever it was in her interest to do so:

> If I cycled from my quarters to the military hospital, where she might have to remain on guard by my bicycle for hours on end, she limped so pitifully that people in the road often reproached me. But if we took the direction of the army riding school, where a cross-country ride was likely to ensue, the pain had gone. The swindle was most transparent on Saturdays. In the morning, on the way to duty, the poor dog was so lame that she could scarcely hobble behind the bicycle, but in the afternoon, when we covered the thirteen miles to the Ketcher See at a good speed, she did not run behind the bicycle but raced ahead of it at a gallop, along the paths which she knew so well. And on Monday she limped again. (181)

From the foregoing anecdotes, it would appear that sympathy lameness is acquired as the result of increased attention given to a dog following a limb injury, with the dog learning to feign discomfort to get attention and affection from its owner (Hart and Hart, 1985), but another possible interpretation is that such behavior may stem from active-submission behavior and conflict (see above), resulting from increased petting and contact between the owner and dog following the injury. Whatever the case, sympathy lameness is a rather uncommon phenomenon, and before attributing an attention-seeking causation to the behavior, it should receive a careful veterinary evaluation. Differential diagnosis should exclude other more common and likely physical causes underlying signs of lameness. Limping should always be interpreted first in terms of a potential physical ailment and, only after such efforts fail to turn up a cause, should the possibility of sympathy lameness be seriously considered. If it is clear that the signs of lameness appear only under emotionally stressful situations, then *maybe* sympathy lameness is occurring rather than a strain, growth pains, or some other physical causation (e.g., Lyme disease).

Assessment and Evaluation

The first step in evaluating dogs with compulsive habits is to obtain relevant information, including a medical history. It is crucial for the consulting trainer to get a detailed picture of the dog's behavior, along with a thorough inventory of the various eliciting stimuli and contexts in which the behavior has occurred in the past, prevailing motivational conditions under which the behavior tends to occur, and the approximate frequency and duration of the behavior's occurrence. Additionally, the owner should be questioned with regard to previous methods used to control the dog's behavior, including both successful and unsuccessful ones. In severe cases involving acute onset, automutilation (self-injury), or seizure activity, the client should be referred to a veterinarian for a medical evaluation.

In many cases, finding a correlation between a compulsive behavior and a specific precipitating stimulus or environmental condition is not possible. In such dogs, a compulsive habit may be under the stimulus control of an internal cue and emitted to modulate a generalized state of frustration or anxious arousal. When such causes are suspected, steps should be taken to reduce adverse emotional arousal. Quality-of-life enhancements that often prove beneficial in reducing stress include increased daily exercise, play and training activities, and daily massage. In cases where a hunger tension is implicated, a dog's feeding can be adjusted by either increasing food intake or increasing the frequency of feedings. Some dogs are benefited by an ad libitum feeding schedule in which they are permitted to eat whenever they wish. Of course, not all dogs can be fed ad libitum without gaining weight, but many dogs can be fed in such a way without experiencing much, if any, significant weight gain. In those dogs where ad libitum feeding is inappropriate, the frequency of measured feedings can be increased during the day.

Compulsive behavior often occurs under the influence of excessive anxiety or frustration elicited by some external stimulus or situation. The most effective training method for managing CBDs involves a combination of graduated exposure, counterconditioning,

and response-prevention procedures. For example, when the CBD is either precipitated or augmented by the presence of the owner or some other specific stimulus, it is often useful to gradually expose the dog to the eliciting stimulus while at the same time blocking the repetitive activity or by eliciting incompatible emotional responding (e.g., relaxation or appetence). In the case of intractable or refractory compulsions involving self-injury (e.g., ALD), aversive counterconditioning and punishment procedures may be effective (Eckstein and Hart, 1996). (Specific treatment recommendations for the control and management of CBDs is deferred for discussion in a forthcoming volume.)

Prevention

The etiology of compulsive behavior is only partially understood. Many dogs exhibiting locomotor compulsions exhibit general hyperactivity and impulse-control problems. Dogs with licking compulsions often exhibit anxious attachments toward their owners, may have suffered the loss of a significant other (animal or human), may be stressed by social competition or rivalry (perhaps involving the introduction of a new pet or baby), or may have undergone long-term neglect and social deprivation.

Compulsive behavior is commonly seen in dogs that exhibit signs of chronic stress, excitability, and insecurity. Such dogs can be provided with a sense of security and well-being by establishing strong leadership and making significant events predictable and controllable. Owners of such dogs should not neglect to establish definite boundaries and enforce them when necessary but should be careful to avoid highly charged emotional interaction triggering chronic fright-flight-fight conflicts. Other sensible precautions and suggestions include

1. Provide the dog with choices during stressful and conflict dense situations.
2. Interact with the dog in predictable, consistent ways, giving the dog a degree of control over what happens to it.
3. When discipline needs to be administered, make certain that appropriate alternative behaviors are prompted and reinforced.
4. Establish a daily regimen of obedience training based on positive reinforcement and play.
5. During training activities, emphasize clear communication and mutual understanding—not simply exercising one-sided control and dominance.
6. Make the dog feel secure in its social relationships by providing adequate daily affection and attention.

Finally, a dog's confidence is enhanced by providing it with structured training and socialization activities from an early age. Such treatment facilitates the development of behavioral optimism, causing the dog to believe that success is always possible, thus effectively immunizing it against acquired learning disabilities (negative cognitive set) and related compulsive habits.

PART 2: HYPERACTIVITY

Hyperactivity versus Hyperkinesis

Excessively active dogs presenting with signs of impulse-control problems and other relevant symptoms (e.g., attention deficits, inability to calm down, persistent reactivity to restraint and confinement, aggressiveness, impaired learning abilities, and insensitivity to punishment) should be evaluated for hyperactivity and possible hyperkinesis syndrome. Dogs exhibiting hyperactivity (especially in those cases presenting with emotional instability, impulsivity, and aggressiveness) may be candidates for treatment with a central nervous system (CNS) stimulant (e.g., methylphenidate) and should be referred for a veterinary evaluation. Increased excitability and hyperactivity may be associated with various disease conditions (e.g., hyperthyroidism) that should be considered as part of a differential diagnosis performed by a veterinarian. In the discussion that follows, I have opted to use the term *hyperactivity* to designate the common form of excessive activity and attention deficits that occur in dogs without physiological concomitants. The term *hyperkinesis* is here reserved for those cases of hyperactivity and attention-impulse deficits that respond to stimulant medication.

SIGNS AND INCIDENCE

Impulse Control and Attention Deficits

Hyperactivity and attention deficits are frequently exhibited by puppies and adolescent dogs presented for behavioral training. These problems are widely distributed among dog breeds but are especially prevalent among hunting and working breeds—dogs selectively bred for enhanced environmental alertness, vigilance, and high activity levels. Affected dogs frequently exhibit an abnormally short attention span and impulsiveness. This attention impairment makes them unable to concentrate on any one thing or task for long before being distracted by something else. Some dogs appear as though everything encountered by them, no matter how trifling or insignificant, is treated with an equally active and fleeting interest. Hyperactive dogs are especially sensitive and reactive to novelty or the presence of unfamiliar persons or animals, often displaying a pronounced inability to habituate to such stimulation. Such dogs appear to be strongly influenced by a diffuse incentive or seeking mechanism that is activated by novelty, with resulting hyperarousal, exploratory and olfactory activity, and exploration-related problems (e.g., destructiveness). Consequently, such dogs may exhibit persistent restlessness and disorganized activity in search of rewarding stimulation. Frustrated owners often complain that their dog "can't sit still" or that it "gets into everything."

Reward, Inhibition, and Delay of Gratification

Another important behavioral manifestation exhibited by hyperactive dogs is their resistance to inhibitory training and physical control. Hyperactive dogs appear to be much less sensitive to aversive stimulation and punishment than are average dogs. Further, they often become even more excitable and unmanageable when efforts are made to constrain them forcefully. On the other hand, they are often very responsive to reward training, but rewards, if they are to work, must be given on a near-continuous basis in order to secure their wavering and easily distracted attention (Sagvolden et al., 1993). If reinforcement is scheduled intermittently or made contingent on the performance of a chain of intervening responses, hyperactive dogs may rapidly lose interest. The impulsive character of hyperactivity is reflected in the affected dog's inability to wait or to delay gratification. Although hyperactive dogs may attend and work well under conditions of continuous reinforcement, they exhibit clear deficits when it comes to situations requiring a long delay before reinforcement is delivered (e.g., a long sit-stay). This pattern is also evident among children with attention-deficit hyperactivity disorder (ADHD) who are easily distracted from deferred goals by the offer of more immediate but smaller rewards. To investigate the role of delay of reinforcement Sagvolden and colleagues (1992) performed a series of experiments with hyperactive rats. They confirmed the rat's preference for short-term reinforcers and the existence of deficits involving delay of reinforcement when compared to normal controls. In addition, they observed that CNS stimulants improved the effectiveness of delayed reinforcers for controlling repetitive operant tasks while simultaneously reducing the distractive strength of immediate reinforcers. These findings are consistent with the observed positive effects of CNS stimulants on impulse control and delay of gratification behavior in both hyperactive children and dogs.

Besides exhibiting a high degree of distractibility, impulsiveness, and various learning deficits, hyperactive dogs are impulsive and often emotionally unstable, possessing a low tolerance for frustration and sometimes exhibiting uncontrollable ragelike aggressive behavior. Parallel symptoms in child psychopathology have been identified and described (Hinshaw, 1994; Werry, 1994).

A biological factor certainly plays some role in the etiology of hyperactivity, but many social and environmental factors also contribute to its expression. Family dogs are especially vulnerable and prone to develop hyperactive behavior as the result of exposure to overly active and playful children. Additionally, hyperactive *play* may develop as an inadvertent result of ineffectual punishment. Although an owner may be quite sincere, the action taken is often attenuated as the result

of affection for the dog or personal inhibitions about such interaction. A dog may misinterpret this self-restraint and *kindness* as an awkward human invitation to play rather than punishment. Active dogs play hard and, while playing, frequently exhibit subdued agonistic challenges and threats that may be ethologically analogous to the owner's ineffectual punitive efforts. Such play is often so intense that it may be confused with real aggression (Voith, 1980a,b).

Etiology

Social and Sensory Deprivation

Waller and Fuller (1961) found that puppies reared under conditions of semi-isolation exhibited excessive compensatory efforts to initiate social contact when permitted to do so. When the puppies were kept with littermates continuously, the number of social contacts was reduced by 75%. These observations suggest that dogs may possess a biological *need* for some relatively fixed amount of daily sensory stimulation, motor activity, and social contact. If these requirements are not met, then various compensatory and excessive efforts may be emitted by dogs to secure them. Clearly, there exists a great deal of individual variability from dog to dog with respect to their specific needs. Just as hypothalamic set points control many basic biological drives like hunger and thirst, it is reasonable to hypothesize that general arousal and activity may be controlled by a similar subcortical homeostatic mechanism (Fox, 1974). According to this theory, dogs are motivationally and behaviorally activated to secure stasis through compensatory and excessive behavior when environmental conditions prevent them from obtaining optimal stimulation or vital resources needed to sustain them.

Hyperactive dogs are often exposed to routine isolation due to their behavioral excesses. This points to another set of contributing factors underlying hyperactivity: inadequate social attention, insufficient or irregular exercise, and excessive confinement. Active dogs subjected to daily crate confinement tend to become increasingly hyperactive and solicitous of attention. When released from confinement, the demands made by such dogs are anything but welcome by family members, who may have all but entirely rejected them as a result of their behavioral excesses. The situation is a vicious circle, with excessive behavior resulting in further rejection and isolation, thereby generating more attention-seeking behavior and hyperactivity. Also, excessive or noncontingent (uncontrollable punishment) may contribute to the development of hyperactive attention-deficit symptoms. A result of such treatment is diffuse vigilance and disorganized responding, especially after startling stimulation or at times associated with a history of unpredictable and uncontrollable punishment.

Adjunctive Generation of Hyperactivity

Attention-seeking and active-submission behavior appear to play a significant role in both hyperactivity and compulsive behavior, perhaps stemming from strong adjunctive-generator influences localizing in affection-fear conflict. As previously discussed, Falk suggests that excessive behavior is likely to result under the influence of conflict-laden *marginal* intermittent reinforcement (see *Schedule-induced Excessive Behavior,* above). It should be noted that both rich and lean schedules of reinforcement are relatively immune to conflict and the adjunctive generation of excessive behavior. In the case of rich reinforcement schedules, conflict is avoided, since consummatory behavior is ascendant, whereas, in the case of lean schedules, conflict is avoided because escape behavior dominates, causing the animal withdraw from the situation. Under the influence of *marginal* intermittent reinforcement, a *conflict* may localize between a consummatory vector and an escape vector of equal strength. Compulsive habits or hyperactivity may result in cases in which marginal intermittent reinforcement occurs chronically. Attention-seeking behavior, for example, may succeed often enough to maintain a dog's effort but not enough to offset an opposing motivational vector to give up trying (escape)—an unlikely outcome, in any case, for a highly dependent and sociable dog.

Active-submission behavior (i.e., attention seeking) may itself become a compulsive activity in its own right. A conflict between

affection and fear is embedded in submission behavior; that is, submissive dogs are simultaneously attracted to and repelled by the object of submission. *Affection keeps a dog in close contact with its owner, preventing the dog from resolving the conflict by running away, but fear prevents the dog from relaxing and fully enjoying the contact. As a result, contact comfort and reassurance may not satisfy a submissive dog, at least, not as long as it is engaged in active submission.* These observations may help to explain why some attention-seeking dogs are so insatiable, never seeming to get enough affection or contact comfort:

> Attention-getting behavior is found in the typical household situation in which the dog is already heavily indulged with love and petting. While it may seem illogical, dogs that are getting the most attention are those that will go to some effort to gain even more. It is probably impossible to satiate a dog with too much attention. Dogs that receive little attention from their owners have the least probability of acquiring this behavioral problem. (Hart and Hart, 1985:85)

Such dogs may engage in persistent licking, pawing, and other proximity-enhancing active-submission behaviors. This situation is very different from other drives, like thirst or hunger, that can be easily quieted by the consumption of food or water. For compulsive attention seekers, the consumption of social contact tends to generate more preparatory arousal (affection-fear conflict), resulting in more attention seeking but failing to quiet the escalating need for comfort and reassurance. Because of its motivational character, compulsive submission behavior is capable of generating high levels of anxiety. Because such dogs are often unsuccessful in their general social efforts, anxiety is joined by frustration to coactively increase activity levels and generate maladaptive and excessive behavior.

As a result, attention-seeking dogs may engage in a variety of adjunctive behaviors, such as destructiveness and hyperactivity. Treating such cases involves either (1) modifying generator conditions (alter the schedule of attention giving) or (2) directing the destructive or hyperactive behavior into more appropriate outlets. Although attention-seeking behavior may occur in close association with a variety of behavior problems, such behavior is probably not emitted as a means to obtain attention per se but as the adjunctive expression of marginal social reinforcement.

Neural and Physiological Substrates

During various classical conditioning studies involving the induction of stress by means of unavoidable aversive stimulation (shock), Corson and coworkers (1973) found that a small percentage of dogs were unable to relax while restrained in an experimental harness. Some of the dogs became so aroused and reactive that they attacked the harness and nearby equipment. These highly reactive dogs exhibited no signs of improvement over several training sessions. Hypothesizing that the symptoms were similar to those exhibited by hyperactive children, the researchers experimented with various CNS stimulants used to control hyperactivity in children. Children affected with ADHD respond *paradoxically* to CNS stimulants. Instead of causing them to become more active and excitable, as one might expect, the stimulants often cause them to become more calm and focused. They found that hyperkinetic dogs responded to amphetamines in a similar way, becoming less active, more focused, and even more affectionate.

Subsequent studies have confirmed many of Corson's original findings. Bareggi and coworkers (1979) have speculated that D-amphetamine enhances the activity of the neurotransmitters dopamine (DA) and norepinephrine (NE). At low doses, dopaminergic systems are activated whereas, at higher doses, both dopaminergic and noradrenergic systems are stimulated. Since high levels of amphetamine are required to generate the paradoxical effect, they reason that both catecholamine systems are probably involved. Recent studies with hyperactive rats and mice show that the differential response of animals to CSN stimulants is present in rodents. As a result, several new animal models of ADHD have been proposed. These models range from hyperactivity exhibited by "spontaneously hypertensive rats" to hyperactivity induced via chemical lesions of the rat brain. In one of these studies hyperactivity in rats was induced by destroying dopamine fibers with neurotoxins

(Kostrzewa et al., 1994). The lesioned rats responded in the typical manner to amphetamine treatment, thereby raising questions about the role of dopamine in the mediation of the paradoxical effects of CNS stimulants. These findings led the researchers to conclude that, in addition to dopaminergic activity, a serotonergic system is also involved:

> DA and 5-HT neurotransmission may mutually modulate spontaneous locomotor activity in rats and inhibit hyperactivity in humans. Either impaired ontogeny or injury of DA fibers, coupled with subsequent impaired ontogeny or injury of 5-HT fibers, may constitute the underlying basis of hyperactivity in ADHD. The effectiveness of amphetamine in controlling hyperactivity in ADHD is similarly thought to be due to the release of 5-HT, either directly or via action of released DA at 5-HT neurons. The implication is that 5-HT agonists, probably of the 5-HT_{2C} class, could prove to useful in treating ADHD. Likewise, if amphetamine is not acting directly on 5-HT neurons, but via DA release, then direct-acting DA agonists could also become useful in treating ADHD. (165–166)

These findings support the *minimal brain dysfunction* theory of ADHD. Important neuroimaging studies of the frontal lobes and basal ganglia also suggest the possibility of an organic etiology underlying hyperkinesis and ADHD.

More recently, ADHD research has explored the possible role of defects in the DA reuptake mechanism, particularly involving DA-transporter molecules located on the plasma membrane of DA neurons. DA transporters mediate the reuptake and conservation of extracellular DA by absorbing and concentrating it within the cytoplasm for later use. Disturbances of transporter activity may cause a higher-than-normal concentration of DA to remain in extracellular fluids, thereby causing increased motor activity, stereotypies, impulsivity, and cognitive deficits. Research with *knockout* (KO) mice (mutants lacking the specific gene responsible for encoding the DA transporter) have revealed a number of interesting findings with respect to the differential roles of DA, hydroxytryptamine (5-HT or serotonin), and NE systems in the expression of hyperkinetic symptoms (Gainetdinov et al., 1999). KO mice have five times as much DA concentrated in extracellular fluids than do normal mice. As a result, KO mice exhibit significantly higher levels of motor activity and show profoundly impaired cognitive abilities. Psychostimulants (e.g., dextroamphetamine and methylphenidate) were found to exert a significant attenuation of hyperkinetic symptoms in KO mice—effects that cannot be attributed to changes in DA-transporter activity. In addition to the aforementioned stimulant medications, the selective 5-HT reuptake inhibitor fluoxetine was found to attenuate hyperactivity significantly in KO mice but had no discernible effect on normal mice. Finally, the investigators selectively activated and inhibited NE transporters, thereby demonstrating that NE plays no significant role in the expression of hyperkinetic symptoms. In addition to the attenuating effects of fluoxetine, they found that treatment with 5-HT precursors [L-tryptophan and 5-hydroxytryptophan (5-HTP)] significantly reduced motor activity and stereotypic behavior in KO mice. Gainetdinov and colleagues conclude that the stimulants commonly used to treat ADHD probably produce therapeutic effects on downstream serotonin transporters rather than directly affecting DA receptors or transporters.

Kenneth Blum and colleagues (1997) at the University of Texas (San Antonio) have reported compelling evidence suggesting that ADHD, as well as a variety of other common impulse problems and conduct disorders (including aggressive behavior), may develop from an inability to obtain sufficient reward by engaging in everyday activities. This condition, referred to as *reward deficiency syndrome* (RDS), is believed to be a genetic aberration affecting dopamine reward pathways, in particular dopamine D2 receptors. In cooperation with several other neurotransmitters [e.g., serotonin, opioids, and γ-aminobutyric acid (GABA)], dopamine plays a central role in the mediation of reward and the experience of well-being. Blum's research group identified a gene variant (A1 allele) that appears to constrain the expression of D2 receptors on the dopamine neuron by 30%. They found that individuals possessing the A1 allele (especially those who are homozygous for it) are at a significantly greater risk of developing a variety

of problem behaviors and appetites [see Singh et al. (1994)], including self-medication (addictions and excessive eating) and dysfunctional behavioral strategies (impulsive and compulsive tendencies), all apparently aimed at achieving improved reward satisfaction.

In the case of dogs, it might be likewise expected that failure to experience reward or well-being as the result of everyday social contact and activity may stimulate affected individuals to engage in impulsive-compulsive behavior and inappropriate appetitive gratification, such as increased attention seeking and pica. The inability of such dogs to achieve internal reward or satisfaction may prompt them to engage in excessive behavior (hyperactivity) seeking sufficient reward. Such a dysfunctional reward mechanism may help to explain why efforts to satisfy affected dogs with attention, exercise, and affection (or food) do not appear to reduce substantially their apparent need for such things. Dogs suffering from RDS may fail to experience social contact as a reward in a consummatory sense, but instead experience it as an incentive or prod to seek more attention or activity. Such dogs may never gain true satisfaction from social interaction because the neural substrates mediating the social reward cascade are not functioning at an optimal level. This is consistent with the observations of Sagvolden and coworkers (1993), who found that hyperactivity was reduced in genetically hyperkinetic rats when they received more frequent reinforcement.

The putative influences exerted by genes regulating the dopamine transporter system on ADHD as reported by Gainetdinov and coworkers seem to conflict with the receptor diminishment hypothesis of Blum and colleagues, suggesting that more research is necessary to uncover the neurobiological substrates controlling the expression of hyperkinesis and related impulsive and compulsive tendencies in dogs. Clearly, though, the dopamine limbic circuits appear to play a significant role in the development of excessive behavior. Interestingly, in this regard, Niimi and associates (1999) at Gifu University, Japan, have reported significant differences in genetic variants controlling the expression of dopamine D4 receptors in golden retrievers and Shibas. The D4 receptor is believed to be involved in *novelty seeking* and other behavioral tendencies depending on the allele (short or long) expressed (Ebstein et al., 1996). In humans, the long allele is not only associated with novelty seeking, but also various personality dimensions, such as compulsiveness, excitability, quick temper, and fickleness, whereas the shorter allele is most often associated with reduced novelty seeking and an opposite set of personality characteristics (e.g., reflective, slow to anger, stoicism). Niimi's group found that the golden retriever was most likely to possess the short A allele (78.9%), whereas the long D allele was most common in the Shiba (46.7%). The D4 receptor is primarily found in the limbic system and expressed in neurons exerting direct effects upon cognition and emotional behavior. These findings support the view that the limbic dopamine system plays an instrumental role in the expression of canine behavioral traits.

Although the neural sites and pathways involved in the expression of hyperactivity (ADHD) are not definitively known, various neuroimaging studies suggest that the caudate nucleus and the striatum (basal ganglia) are involved to some extent (Hynd and Hooper, 1992). Both of these sites project to frontal lobe areas involved in the regulation of locomotor activity and impulse control. Studies with children exhibiting ADHD indicate that both the caudate nucleus and the striatum show low metabolic activity and blood flow—a condition that is ameliorated by the administration of methylphenidate and reversed as the drug wears off. Another distinguishing neuroanatomic feature of childhood ADHD is the finding that affected children do not exhibit the typical frontal lobe asymmetry (right > left) of normal children but instead tend to exhibit symmetrical (right = left) frontal lobe widths. Further, it has been found that hyperactive children have significantly narrower right frontal lobe widths than children not exhibiting ADHD (Hynd and Hooper, 1992).

Relevant studies were performed by Sechzer (1977) on split-brain kittens. The split-brain preparation involves surgically severing the corpus callosum (a large structure of interconnecting fibers communicating between the right and left hemispheres) and

the striatal pathways connecting the right and left caudate nuclei. Split-brain kittens exhibited a constant, poorly focused hyperactivity not seen in normal kittens. At 6 months of age, kittens were injected with D-amphetamine and observed for behavioral changes. Striking reductions in general activity levels and distractibility were immediately seen, but hyperactive symptoms returned within 2 hours after the injection. At 1 year of age, normal and split-brain cats were compared in terms of their respective abilities to learn a simple discrimination task. As observed in hyperkinetic dogs, split-brain cats only very slowly habituated to the training environment, made frequent attempts to escape, and exhibited a high degree of distraction toward external noises. The results of discrimination training showed that split-brain cats were consistently slower than normal cats at learning the task. However, when split-brain cats were medicated with D-amphetamine, they learned the task slightly more rapidly than normal counterparts.

CNS-stimulant-response Test

Some authors have recommended a stringent diagnostic procedure for determining a dog's candidacy for stimulant therapy. The stimulant-response test is administered by challenging the dog with a dose of D-amphetamine and observing various physiological parameters (Luescher, 1993a). The dog's general activity level, demeanor, and various physiological parameters are observed. Hyperkinetic dogs respond to CNS stimulants paradoxically; that is, they calm down and become more focused. The stimulant-response test is performed by taking a baseline measurement of a dog's activity level, reaction to restraint (holding the dog in sit or down position), heart rate, and respiration rate, and (more rarely) salivary and urinary output are measured. Following an oral dosage of D-amphetamine, hyperkinetic dogs will tend to calm down, accept restraint more readily, and exhibit a generalized decrease in the aforementioned physiological measures (Voith, 1979). These effects usually take place within 2 hours—sometimes within 30 minutes after dosing a dog. Dogs that do not respond may require a higher challenge dose. Voith (1980c) describes a method whereby the dose is increased by small amounts every 24 hours until the dog either becomes more active or begins to calm down. Dogs that respond by becoming more active and uncontrollable are not candidates for stimulant therapy. Although a real diagnostic entity, and perhaps underdiagnosed, true hyperkinetic syndrome probably does not occur at the frequency suggested by Campbell (1973, 1992), who claims that 75% of "hyperreactive" dogs given the stimulant-response test show positive results.

A study with hyperactive rats selected from a natural population offers an additional diagnostic dimension for evaluating hyperkinesis with attention deficits. Kohlert and Bloch (1993) observed that rats (not specifically bred for hyperactivity) frequently exhibited signs of hyperactivity similar to those presenting with ADHD. They found that a subpopulation of hyperkinetic rats can be easily isolated through a simple screening process involving three criteria: (1) presence of hyperactivity, (2) positive attenuation of activity levels in response to amphetamine, and (3) decreased ability to attend selectively to relevant stimuli during avoidance training. The study included an interesting test procedure for quantifying a subject's relative ability to attend selectively, that is, to pay attention to relevant cues while ignoring irrelevant ones. Disturbances of selective attention are frequently implicated in the diagnosis of hyperkinesis, but, unfortunately, objective criteria for its assessment have not been devised for dogs.

Dietary Factors and Hyperactivity

Several studies have investigated the possible role of food additives and colorants in the development of ADHD in children. Most of this research has been unable to find a convincing causative link between ADHD and the various agents studied (Weiss, 1991). Likewise, among dogs, no scientific evidence exists to date supporting the popular belief that additives and colorants cause hyperactivity and other behavior problems. A study performed by Barcus and coworkers (1980) failed to show a causal linkage between FD&C red

dye 40 or butylated hydroxyanisole (BHA)—substances suspected (but not proven) to play a role in the etiology of childhood ADHD—and hyperkinesis in Telomian hybrid dogs. Although the study failed show a direct linkage between red dye 40 and BHA in the development of hyperactivity, it should be noted that during a 28-day additive-free transition period all dogs exhibited a sharp decrease in hyperactive symptoms. Recent studies involving children have also discounted the role of excessive amounts of sugar and development of hyperactivity (Hynd and Hooper, 1992). However, studies with rats suggest that increased levels of dietary carbohydrates (including sugar) relative to decreasing protein intake results in the expression of higher activity levels (Spring, 1986).

Another potential source of hyperactivity in dogs is chronic lead poisoning. Two common sources of such poisoning are destructive chewing on linoleum or surfaces painted with lead-based paints. Silbergeld and Goldberg (1974) induced hyperkinetic symptoms in mice by exposing them to lead. The hyperkinetic symptoms were palliated with high doses of D-amphetamine. A large study performed by Thomson and colleagues (1989) found a positive correlation between lead blood levels and aggressive-hyperactive tendencies in children. Puppies exposed to lead should be tested and appropriately treated.

Inadequate nutrition may permanently affect general activity levels, especially when deprivation occurs early in life. Michaelson and coworkers (1977) found that hyperkinetic symptoms could be induced by manipulating dietary intake during a critical period for brain growth in mice. Mice were divided into two groups: group-I mice were raised in large litters in which 16 young were placed with a single mother (starved). Group-II mice were raised in small litters of 8 animals per nursing mother (controls). At 35 days of age, the two groups of mice were compared with regard to general activity levels and their response to D-amphetamine. Following a brief period of adaptation, starved rats exhibited a higher level of activity when compared with well-nourished controls. Upon administration of D-amphetamine, the starved rats became less active than the controls, a trajectory of decreasing activity that continued to develop into the following hour after medication. Growth-retarded mice exhibited a strong paradoxical effect to D-amphetamine. These observations emphasize the importance of good nutrition during early growth periods in puppies. Breeders should be especially careful in their management of puppies belonging to large litters or those being nursed by a mother unable to produce sufficient nutrition through lactation alone. Further, the mother's dietary intake should be carefully evaluated and adjusted to meet the demands of nursing her litter.

TWO CASE HISTORIES

Jackson

A collateral discovery made by Corson and colleagues (1973) was the pronounced effectiveness of D-amphetamine for the control of aggressive behavior. A cocker spaniel-beagle mix named Jackson, described as being "incurably" vicious toward other dogs and people, responded dramatically to medication with D-amphetamine. Tranquilizers like chlorpromazine and meprobamate did not reduce the dog's aggressive behavior; however, an oral dose of D-amphetamine "within a period of 1 hr dramatically transformed the incorrigible, vicious, antisocial warrior into a peaceful, cooperative, lovable dog" (687). These effects lasted for up to 7 hours. An initially exciting aspect of CNS-stimulant therapy of hyperkinesis-related aggression was the finding that, after 6 weeks of drug and "psychosocial" therapy, the previously uncontrollable aggressive behavior largely disappeared and remained in remission even once the drug was withdrawn. Corson noted that no tolerance to the drug was observed during the treatment period. These early hopeful prospects have not been borne out by subsequent clinical experience, however.

Barney

In an anecdotal report, Jenny Drastura (1992) describes her personal experiences with a hyperkinetic male Lhasa apso named Barney that had developed a serious aggression problem. Even as a puppy, Barney exhibited incip-

ient signs of a developing aggression problem. He resented being rolled onto his side and resisted various other forms of restraint and grooming. By the time he was 16 weeks of age, he began snapping during routine disciplinary interaction—discipline that involved verbal reprimands only. Barney proved recalcitrant to formal obedience training, biting his owners on three separate occasions while being trained. He was subsequently exposed to a more positive training process, employing food reinforcement and other rewarding activities in exchange for cooperation. Under the influence of such training, Barney proved much more compliant, but his aggressiveness continued to worsen. By the time he was 2 years old, it had become a serious behavior problem:

> Not only did he growl and snarl when challenged on his own turf, he was also beginning to go into a "ragelike" state any time he perceived that he was being threatened. In his rage state, he would withdraw into himself, growling and snarling, actually appearing to become smaller. His growling turned into screeching noises, his eyes appeared red as blood filled the blood vessels in his eyes and his gums turned white. Finally he reached a stage where he could not withdraw any further, and he attacked any object directly in front of him at about a 12 inch range. He appeared to have no peripheral vision. Oddly enough, this rage ended instantly if we yelled "cookie" or "cheese." His body relaxed and he immediately began jumping or dancing for whatever we had promised. It appeared that he had no idea what had just happened to him. (20)

As Barney's condition deteriorated, the owners contacted Victoria Voith for suggestions and guidance. Voith treated Barney with a combination of behavior modification and a panel of psychotropic drugs in an effort to control his ragelike aggressive symptoms. After a series of false starts and dead ends, it was found that Barney's aggressive symptoms were relieved by D-amphetamines. Barney was prescribed D-amphetamine to be taken twice a day. He responded to the medication by becoming more affectionate, more playful, and much less aggressive. The results were strikingly consistent with those described by Corson and coworkers in the case of Jackson.

Two significant divergences occurred between Corson's findings and the behavior of Barney regulated by D-amphetamine: (1) When Barney was taken off medication, his aggressive behavior returned. In Jackson's case, Corson observed a radically different therapeutic course. Instead of recovering after medication was discontinued, aggressive behavior remained quiescent. (2) Corson reported that dogs treated with D-amphetamine did not develop a tolerance to the drug. Barney did develop a tolerance to the drug (albeit after 3 years of treatment). He also exhibited a clear dependency on it. For instance, when he was periodically taken off the stimulant or when the drug simply wore off, he would become even more aggressive than he had been before treatment with the medication. Such heightened aggressiveness may have been the result of a combination of withdrawal symptoms and various neurological side effects of long-term D-amphetamine therapy. It should be noted that Barney exhibited other signs of neurological deterioration, including the development of various repetitive stereotypic behaviors (e.g., chomping with nothing in his mouth) and episodes of bizarre and inexplicable barking episodes.

Cognitive Interpretations and Speculation

Hyperactive dogs appear to be unable to modulate sensory input and to coordinate it with an integrated behavioral output. As the result of such cognitive impairment, a dog may attempt to keep pace and adjust to the changing environment by speeding up its behavior, increasing vigilance, or by intensifying its behavioral efforts to control fleeting events. Viewed from the perspective of a *minimal brain dysfunction,* the observed symptoms of hyperactivity are really the dog's best efforts to establish control over the slippery and transient stimulus events impinging on it.

Stimulus events reaching the attention of such dogs appear to compete for equal and undivided attention, suggesting a failure of cognitive functions dedicated to selectively collecting and processing sensory data and transforming it into information. Under normal conditions, a complex neural *gating* and

comparator system serves to separate relevant from irrelevant sensory input, thus enabling dogs to match their behavior to changing circumstances. Sensory input is conditioned by at least three basic stimulus and contextual dimensions: (1) stimulus sequencing, (2) event boundaries and frames, and (3) figure/ground relationships. In the case of an inadequacy involving stimulus sequencing, dogs may not be able to sufficiently order events along a temporal dimension from which to derive causally meaningful relationships between them. In other cases, a dog may not be able to determine where one stimulus event begins and where another ends. In this case, the stimulus event is inadequately bounded and framed for cognitive representation and, therefore, insufficiently distinct to hold the dog's attention. Lastly, a dog may not be able to place stimulus events (although temporally well ordered and defined) into a spatial context in which they can be perceived as distinct and separate events set against a contextual backdrop. In this case, the event is obscured by competing and irrelevant background information. Of course, all of this is highly speculative but does provide a tentative framework for evaluating possible cognitive-perceptual impairments in hyperactive dogs.

An apparent exaggerated need for novelty and variety is a characteristic feature of many hyperactive dogs. They may be affected by an intolerance for boredom. In fact, some evidence suggests that hyperactive animals may actually be more intolerant of repetitive demands than are normal ones (Mook et al., 1993). Under experimental conditions where behavioral variability is rewarded, hyperactive rats may excel over normal controls. However, in situations requiring repeated performance of a similar response, hyperactive rats show clear signs of a disadvantage or learning deficit. On the positive side, these findings seem to imply that hyperactive animals are better adapted to situations requiring *creative* solutions. Perhaps an evolutionary pressure exists that alternately favors both general styles of learning, depending on changing demands placed on an animal by the environment. In times of change and crisis, a *creative* animal (greater behavior variability) would enjoy a distinct biological and adaptive advantage over its more routine-oriented counterpart. These general findings suggest that hyperkinesis may serve a legitimate and important behavior-diversifying function. This line of reasoning leads to a novel appreciation of the biological and cultural significance of ADHD in children and hyperkinesis in dogs.

Behavioral Side Effects of Hyperactivity

Many comorbid complications and long-term side effects frequently develop in the wake of hyperactivity. Affected dogs are often so behaviorally disorganized that normal developmental processes are adversely impacted. A striking characteristic of most hyperactive dogs is their immaturity. Because hyperactive dogs find it difficult to control their impulses, they are subjected to a high degree of frustration and other emotional tensions. It is interesting to note in this respect that hyperactivity is often most exaggerated during social encounters where such excesses result in a great deal of interactive punishment, disapproval, and rejection. An owner may also become progressively frustrated and respond by escalating punitive efforts or by relying on increasing amounts of isolation in order to manage a hyperactive dog's behavior. Since many attention-seeking behaviors are *active-submission* efforts, threats or physical punishment may serve only to stimulate even *more* of the unwanted behavior in a futile effort to appease the owner.

Not surprisingly, frustrative arousal is often associated with social excesses and hyperactivity. Dogs that are unable to achieve a satisfying social connection with their owners may, as a consequence, try even harder. Unfortunately, the dogs' efforts are rarely successful, and repeated failure may lead them to form corresponding negative expectancies about future efforts. In such cases, frustration is evoked by both obstructed access to the social goal, as well as a failure or deficiency of a dog's behavioral repertoire to achieve it. An expectation of failure may consequently evoke frustrative preparatory arousal whenever the dog is in the owner's presence. Consequently, the dog's moment-to-moment expectations of

pending failure in social settings may stimulate a spiraling escalation of frustration and corresponding social excesses. The thwarted social intentions and motivations underlying unsuccessful social excesses provide a powerful locus for escalating frustration and anxious arousal in the form of attention seeking (i.e., excessive active-submission behavior). Problematic attention-seeking behavior may reflect persistent social frustration, resulting in disorganized and ineffectual social behavior, especially involving active submission. Attention-seeking dogs are not usually satisfied with getting social contact, and giving it to them may only evoke additional compulsive attention-seeking behavior, suggesting the presence of other motivational imperatives at work, besides the satisfaction of proximity or contact needs. Punishment in such cases appears to escalate attention-seeking efforts, underscoring the submissive character of such behavior—the punitive efforts simply serve to evoke more active-submission behavior. Punishment may be effective only if it results in passive submission. Interestingly, such dogs are often highly responsive to shaping procedures using positive reinforcement in combination with time-out, with brief isolation serving to calm them (see *Time-out and Social Excesses* in Volume 1, Chapter 8). The calming effects of brief time-outs away from the owner may work because the procedure removes (stimulus change) the operative cue (the owner) controlling frustrative submission behavior and restores contact only after the dog has calmed down (passive submission).

Aggressive Behavior: Basic Concepts and Principles

But where danger is, grows
The saving power also.

FRIEDRICH HÖLDERLIN, *POEMS AND FRAGMENTS* (1966)

PART 1: INTRODUCTION

CHARACTERISTICS OF DOGS THAT BITE: AGE AND SEX

The etiology of aggressive behavior presents considerable variation from dog to dog. Aggressive behavior is most frequently exhibited by socially mature and intact male dogs (Reisner, 1997), but young puppies can have serious precocious aggression problems, as well. Mugford (1984) reported that among 50 English cocker spaniels the mean average age of dogs with dominance-related aggression was 7.4 months (range, 3 to 24 months). In another group of golden retrievers treated by

Mugford (1987), 24 with aggression problems averaged 2.9 years of age (range, 0.7 to 8.0 years). Of the 24 dogs treated by Mugford, 19 were males, two of which had been castrated. Beaver (1983) found that of 120 dogs with aggression problems (various diagnoses) the mean age was 3 years (range, 9 weeks to 11 years). She reported that 60.1% of the dogs were intact males (14% castrated), with 15.4% intact females (10.5% spayed). Wright (1985) found that the average age of dogs involved in severe attacks was 3 years (range, 0.67 to 10.5 years). All 16 dogs were males. These statistics suggest that considerable variation exists with respect to the time of onset associated with aggression problems. Although most dogs are presented for treatment at 1 to 3 years of age, incipient signs of a developing problem are frequently observed in young puppies, often prior to 4 months of age.

INCIDENCE AND TARGETS OF AGGRESSION

Although a number of studies indicate that dog bites against people represent a serious problem, perhaps even having reached epidemic proportions (Lockwood, 1996), the available statistics are incomplete and inadequate. A notable problem is the dog population sampled. Many of the statistics discussed below were obtained from urban populations that may be skewed by a disproportionate number of aggressive, guard-type dogs. Harris and colleagues (1974) note that urban dwellers frequently keep and socialize aggressive dogs to enhance home security in high-crime areas. Also, the number of social contacts in which bites might occur are probably substantially more numerous in the city than in the suburbs or the country. Consequently, it is difficult to draw any hard and fast generalizations, outside of those directly related to the particular populations sampled. In contrast, the statistical information concerning fatal dog attacks is considerably more reliable and complete. What is extraordinary about fatal attacks is the relative rarity of such incidents when considered in the context of the many millions of intimate contacts occurring between dogs and people every day. Statistically, a child's life is far safer in the presence of its family dog than in the hands of human caretakers or parents.

Overall Situation: Total Number of Bites and Implications

The overall number of dog bites occurring in the United States is widely disputed among reporting authorities. These differences of opinion are attributable (in part) to statistical errors stemming from erroneous population estimates [see Mathews and Lattal (1994)], inconsistent definitions of what constitutes a dog bite, the absence of a consistent and reliable method for tallying dog-bite incidents, and widespread underreporting of dog-bite incidents. A task force on aggression, organized by the American Veterinary Medical Association (AVMA) (Golab, 1998), found that there is a need to standardize the ways in which dog bites are reported. The task force has suggested that standardized forms be produced for collecting information about the age of the bite victim, the circumstances of the incident, the extent of the injuries, and the signalment of the dog. In addition, the task force hopes to better define legal requirements for reporting dog bites and to develop better means for collecting and keeping dog-bite statistics. Unfortunately, the AVMA task force did not include a professional dog trainer—a significant oversight, since most owners with dog-aggression problems turn to such people for advice and guidance.

Despite the inherent limitations involved and the risk for erroneous generalizations, a careful study of relevant statistics is revealing and useful. According to the AVMA (1997), approximately 52.9 million dogs live in the United States. The AVMA figure is somewhat lower than the Pet Food Institute's (PFI) (1999) estimate of 57.6 million dogs, with approximately 37.6% of all American households keeping at least one dog. Calculating the number of dog bites is a much harder statistical task, with the current best guesses ranging from 2 to 5 million dog bites occurring each year. Pinckney and Kennedy (1982) estimated that approximately 2 million people are bitten each year in the United States, with a tenth of these victims requiring sutures, a third missing time away from school or work,

and half receiving permanent scarring as the result of their injuries. Since many minor bites and bites delivered by familiar dogs are not reported, the actual number of dog bites is probably higher than this conservative estimate. In 1996, Sacks and colleagues (1996a) at the National Center for Injury Prevention and Control estimated that approximately 4.7 million people are bitten in America each year. Of these victims, 899,700 persons required medical attention. They estimate that children were 1.5 times more likely to be bitten, and over 3 times more likely to require medical treatment than adults. Besides the emotional and physical pain of dog attacks to the victims, dog bites represent a serious legal and monetary liability to dog owners. The Insurance Information Institute (1999) estimates that dog bites cost the public approximately 1 billion dollars per year in losses, with insurance companies paying out $250 million to resolve dog-bite claims in 1996. State Farm Insurance (1999) alone reported paying nearly $80 million in dog-related liability claims in 1997. According to State Farm Insurance, one in three homeowner claims involving personal injury pertain to a dog bite, with an average payout of $12,000 per bite incident.

Vital Characteristics: Age, Sex, Risk-taking Propensity, Location of Attacks, Time of Day/Season, and Bodily Target of Attack

Children are bitten at a disproportionate rate when compared to other population groups (Gershman et al., 1994). It should be noted in this regard, however, that children are also most commonly associated with homes that keep dogs as pets (Marx et al., 1988; Wells and Hepper, 1997). Approximately 1% of all children brought for emergency treatment are victims of dog bites (Brogan et al., 1995). Adams and Clark (1989) found that 38% of 105 dog owners interviewed reported that their dog had "nipped" at children or had bitten someone—62% of these bites were directed toward family members. The majority of dog bites are directed toward children 5 to 14 years of age (Riegger and Guntzelman, 1990).

Boys are bitten nearly twice as often as girls (Harris et al., 1974). Boys also receive the majority of severe bites (60% to 78%) (Wright, 1991). Sacks and coworkers (1989) found that, among 29 children between the ages of 5 and 9 who suffered a fatal dog attack, 23 (79.3%) of them were boys. The first clear sign of a sexual differentiation of victims is evident in the 1- to 4-year-old group, with 64.2% of the them being boys. A possible explanation for this difference may be due to the amount of time spent by boys versus girls interacting with dogs. Lehman (1928) performed a large statistical study involving 5000 respondents to determine how children spent their time playing. Children of various ages were asked to respond to a series of questions regarding their daily play activities. He found that boys tended to spend more time interacting with dogs than girls did, with both groups showing a steady decline in the amount of time spent playing with pets (both dogs and cats) as they matured. Another possible cause for the uneven distribution of dog bites between boys and girls may be attributable to a boy's greater inclination to engage in risk-taking behavior (Ginsburg and Miller, 1982).

Most bites occur during the summer months (peaking in June) and weekends. On the average day, they are most frequent from 1:00 to 9:00 PM, peaking between 3:00 and 7:00 PM (Harris et al., 1974). Wright (1990) has also reported seasonal and time-of-attack trends. Among 1724 dog bites reported in Dallas, the incidence of attacks peaked between March and May, with 34.6% of the bites occurring during those 3 months. The majority of dog bites (55.8%) took place from 2:00 to 8:00 PM, peaking between 5:00 and 6:00 in the late afternoon. Sacks and colleagues (1989) were unable to detect a similar seasonal trend in the case of fatal dog attacks. Fatal attacks involving pet dogs were actually more common in the winter, whereas stray-dog attacks occurred more often in the fall and least often in the summer.

The majority of bites involving young children are directed toward the face and head, with children under 4 years of age being bitten in the face, head, or neck 63% of the time (Chun et al., 1982; Podberscek

et al., 1990). Beck and colleagues (1975) found that 35% of the bites involving children younger than 4 years of age were directed toward the face. In children between 5 and 9 years of age, this pattern shifts dramatically, with 84% of bites being directed toward the extremities or torso and 18.5% toward the face or neck (Beck et al., 1975). Among a population of children receiving severe injuries, 82% of the bites were directed toward the victim's head or neck.

Dog-bite reports analyzed by Wright (1991) indicate that 87.5% (range, 85.5% to 89.4%) of the dogs involved are owned, with attacks being directed toward family members in 10.5% (range, 5.9% to 15%) of the cases. These estimates probably underrepresent the actual number of persons bitten by their own dog. In a large study involving 3200 children between the ages of 4 and 18 surveyed, 45% had been bitten by a dog at some point in their life. About half of these children were bitten by a neighbor's dog, whereas nearly a third reported being bitten by the family dog (Jones and Beck, 1984).

Emotional Trauma of Dog Attacks on Children

Surprisingly, Jones and Beck found that the experience of being bitten had little effect on the person's later preference for the dog as a pet. This finding has significant implications for the study of cynophobia, since one would expect from the classical conditioning model of fear that a dog bite should have a lasting negative impact on a child's attitude toward dogs.

In fact, some recent and better-controlled research appears to indicate that there exists a significant independence between having experienced a dog bite as a child and the later development of cynophobia or fear of dogs. Two studies are of particular interest in this regard. First, DiNardo and coworkers (1988), utilizing heart-rate changes as a physiological measure of anxiety, were unable to detect a relationship between a previous dog bite and increased physiological arousal when people were tested in the presence of a friendly dog. Second, Doogan and Thomas (1992) found that most cynophobic adults report that their fear of dogs began in childhood, but there is no clear correlation between the frequency of attacks in childhood and the subsequent development of fear toward dogs. The most important factor in the etiology of such fear is the amount of contact that a person had before the onset of fear. People having minimal contact with dogs as children are more prone to exhibit fearfulness as adults. The researchers suggest that prior "noneventful" exposure to dogs may impede the development of phobic reactions in response to dog bites and other sources of fear (e.g., inimical warnings about dogs):

> The role of conditioning events in producing fear of dogs must be considered as nonproven. If such conditioning events do play a causal role then it is only in conjunction with some other factor such as lack of prior uneventful exposure to dogs or in especially susceptible individuals. The present results from children suggest that information transmission may be more important in engendering fear of dogs than studies of adults might suggest. Although most fearful adults report that their fear of dogs began in childhood, it is clear that not all dog-fearful children grow up to become dog-fearful adults, which raises the question of why some children, but not others, eventually lose their fear of dogs. (393–394)

Dogs That Kill

Of particular concern for parents is the possibility of a fatal attack being directed toward an infant or toddler. Although such attacks occasionally occur, most serious attacks are directed toward older children, especially boys. Voith (1984) believes that the majority of fatal or serious attacks directed toward infants are probably instigated by aberrant predatory motivations rather than by sibling rivalry or other commonly cited motivations such as jealousy. Most fatal dog attacks are delivered by dogs known to the victim or the victim's family, with the majority of them being delivered by the family dog or a neighbor's dog. Most of the dogs involved had no prior history of aggressive behavior and attacked without known provocation by the victim (Pinckney and Kennedy, 1982).

FIG. 6.1. These dogs do not fit the stereotypic profile of dogs that might be expected to kill, but they, together with two others not pictured, fatally injured an 81-year-old invalid woman. (Photo courtesy of V. L. Voith.)

It should be emphasized that fatal dog attacks on babies are extremely rare. From 1979 to 1988, the total number of infants (birth to 11 months old) killed as the result of a dog attack in the United States was 25. Children at the greatest risk for exposure to a fatal dog attack belong to the 1- to 4-year group, with 56 toddlers dying from dog attacks over that same period (Sacks et al., 1989). A more recent study by Sacks and coworkers (1996b), covering the years from 1989 to 1994, reported a total of 109 bite-related fatalities, with 57% of the deaths involving children under 10 years of age. Another age group at a higher risk is the elderly, with 18% of the fatal attacks involving persons over 70 years of age (Figure 6.1). The researchers found that 77% of the fatalities involved attacks occurring on the owner's property, with 18% of the dogs restrained and 59% of them unrestrained. Overall, the death rate involving fatal dog attacks has remained relatively constant over the past 16 years, with approximately 15 to 18 fatal dog attacks in the United States each year.

Dog Attacks versus Human Fatal Assaults on Children

Despite the tragic occurrence of dog attack fatalities, the average child is at a far greater risk of being seriously hurt or killed by a parent or relative than by the family dog. A recent report compiled by the U.S. Department of Health and Human Services (1999) found that 1196 children were killed in the United States as the result of maltreatment in 1997. An earlier government study placed that number closer to 2000; that is, approximately 5 children every day lose their lives to maltreatment and child abuse homicide (U.S. Advisory Board on Child Abuse and Neglect, 1995). Over 85% of the perpetrators are either parents (75%) or relatives (10%) of the victim. In addition to deaths, nearly 1 million children experience substantiated or indicated abuse and neglect annually. According to the USDHHS study, children 3 years of age or younger accounted for 77% of the reported fatalities. By way of comparison with dog attack fatalities, according to the aforementioned study

performed by Sacks and colleagues (1996b), during the 5 years between 1989 and 1994, 45 children (from birth to 4 years of age) were killed by dogs. During a similar length of time, extrapolating from the foregoing statistics for 1997, among children 3 years or younger, an estimated 4605 were killed by humans. Given that approximately nine children of this age group are killed by dogs each year, these sobering statistics of child-abuse homicide reveal that it would take dogs over 100 years to kill as many children as are killed by their own parents, relatives, and other guardians on an annual basis. In other words, in any given year, children at greatest risk of abuse are 100 times more likely to be killed by a parent or relative than by the family dog.

Voith and Borchelt (1985) state the threat of serious dog attacks on children in a fair and balanced way:

> Few infants are severely injured by dogs, and the number of infants killed by dogs is very small, probably no more than 10 per year throughout the entire United States. In contrast, many thousands of infants in the U.S. are victims of automobile accidents, burns, drowning, choking, suffocation, and poisoning. It has also been estimated that each day in the U.S. one child under 10 years of age is killed in a handgun accident. Despite the small risk, there is still cause for concern about a dog's reaction to your infant and precautions are well worthwhile. (4)

When fatal or severe dog attacks occur, the situation is often exploited by "expert" media pundits who frequently fail to emphasize the statistical rarity of such anomalies, while pandering to the public's morbid interest in the gruesome details. Overall, the effect is to produce terror and media hysteria over a widespread threat that does not exist. Such incidents predictably spawn demands from dog-hating politicians and other busybodies for immediate action, including stronger animal control regulations and unfair legislation restricting dog breeding and ownership. Obviously, efforts must be made to educate the public about the risk of dog bites and how they can be prevented, but this can be accomplished without resorting to alarmist, unfair, and divisive breed-specific legislation punishing innocent dogs and owners for the actions of a few culpable and irresponsible offenders.

Despite the gloomy appearance of the foregoing statistics, most epidemiological studies have found that the majority of dog bites result in minor physical injury (Podberscek et al., 1990). In a major study by Parrish and colleagues (1959), 88% of the bite injuries treated were judged to be minor, with 2% producing no evidence of injury. This is not to say that serious attacks do not occur—they do and all too frequently—but the majority of dog bites are neither life-threatening nor disabling for the victim. Although dog bites result in relatively minor injuries, it is important that efforts be taken to prevent such attacks. These efforts should include appropriate education for both children and parents (Mathews and Lattal, 1994). Other key preventative measures include early training and socialization of dogs, responsible breeding and selection of dogs that are destined for homes with children, and early behavioral intervention when problems first appear. In addition, children should be taught how to interact more safely with dogs, and parents should become better informed about how to control their children around dogs.

BASIC CATEGORIES

Aggressive behavior is expressed in one of three general ways: threat, defense, or attack. The sort of aggression that a dog exhibits depends on its motivational state and the presence of significant triggers. Konorski (1967) divides aggressive behavior into two general types, depending on the behavioral traits of the organism and the environmental or motivational circumstances present at the moment of arousal (see *Preparatory and Consummatory Reflexes* in Volume 1, Chapter 6). He notes that the same trigger stimulus may elicit either fear or anger in the stimulated animal and consequently result in either defensive or offensive actions. For example, painful stimulation may evoke a massive fear-and-escape reaction in a solitary animal, whereas if the animal is in the presence of a companion, the same stimulation could result in an angry offensive attack (Ulrich and Azrin, 1962). Konorski also points out that the differential display of defensive or offensive behavior is strongly influenced by envi-

ronmental circumstances, noting that an animal threatened on its own territory is more likely to become angry and engage in offensive aggression, whereas the same animal may show fear and react defensively if threatened while in an unfamiliar place. Fear- and anger-elicited attacks are forms of affective aggression, both involving the presence of a high degree of emotional arousal. As is discussed in greater detail below, affective aggression is distinguished from predatory or *quiet-attack* behavior.

Krushinskii (1960) argues that defensive behavior in dogs presents in two characteristic ways: passive and active defensive reactions. Passive defensive reactions take the form of fear and include all types of freeze and flight responses elicited, for example, by loud-unfamiliar sounds or the close presence of strangers. An active defensive reaction, or what Pavlov refers to as a "watch reflex," is expressed in two forms: (1) defensive barking without an effort to bite or (2) defensive behavior that includes an effort to bite. According to Krushinskii, the dog's active and passive defensive behaviors are the result of a combination of various *unitary reactions* that are coordinated to produce complex behavioral patterns having biological significance for the dog as a species. Unitary reactions are variably composed of both conditioned and unconditioned reflexes. However, unlike individual conditioned and unconditioned reflexes, whose pattern of expression is apparent from the beginning (stimulus) to end (response), the unitary reaction is only fully recognized during the final stages of its expression. Unitary reactions are functionally integrated and organized into species-typical behavior patterns and *epigenetic routines* in order to perform various social and biological functions efficiently by means of interacting with the environment. Consequently, although conditioned and unconditioned reflexes variably influence behavioral thresholds (e.g., fear and anger), the functional significance of defensive unitary reactions only become evident as they are organized into integrated species-typical patterns of active and passive defensive behavior.

In general, two broad categories of aggressive behavior exist, intraspecific and interspecific, depending on whether the aggression is directed toward conspecifics or toward other animals not belonging to the aggressor's species, respectively.

Intraspecific Aggression

Intraspecific aggression consists of both ritualized and overt forms of aggressive behavior directed toward conspecifics, that is, individuals belonging to the same species. Most intraspecific aggression is highly ritualized and serves some biologically significant function (e.g., social organization, population dispersion, or sexual selection). In general intraspecific aggression provides a countervailing and distance-increasing function over place and social attachment processes but without breaking down affiliative contact altogether. As such, ritualized intraspecific aggression imposes social order (e.g., the formation of a dominance hierarchy) and territorial limits on the interaction between individuals belonging to the same species. This ordering and distancing function of aggression is especially evident among familiar individuals belonging to the same social group. Whereas aggression directed toward conspecifics belonging to the same group is often highly ritualized and inhibited, aggression toward conspecific outsiders is usually not so well inhibited and may, as among wolves, result in an overt attack and the intruder's death if it cannot put up an adequate defense or escape by running away.

Interspecific Aggression

Interspecific aggression refers to aggressive behavior directed against another species and includes both offensive and defensive elements. Although intraspecific aggression is most often associated with competition between closely socialized animals belonging to the same species, interspecific aggression is most frequently associated with self-protective goals, as, for example, occur when a prey animal defends itself against the attack of a predator. The dog's relationship with humans is complex in this regard, with both competitive and self-protective aggression being exhibited under different situations. Many ritualized

elements of intraspecific aggression are shown toward people with whom dogs are closely socialized. On the other hand, dogs may also exhibit defensive behavior aimed at self-protection and having nothing to do with the establishment of dominance and territory, as appears to be the case in most forms of intraspecific aggression. In the absence of adequate socialization, interspecific aggression predominantly consists of defensive behavior, lacking ritualization and inhibition, and performed with the intention of doing damage.

Many forms of aggression classified as dominance related (see Chapter 8) may be more defensive than offensive. For example, Line and Voith (1986) report that the majority of attacks by dogs diagnosed with dominance aggression occurred while the dogs were being disciplined. Some dogs may interpret human disciplinary actions (hitting, slapping, kicking) as physical threats and react aggressively in an effort to defend themselves. Predatory behavior is often viewed as a form of interspecific aggressive behavior, but, as will be discussed momentarily, predation is not influenced by the same motivational substrates mediating the expression of competitive and self-protective (affective) aggression. In fact, affective and predatory aggression appear to have evolved under independent pressures and are regulated by relatively distinct and segregated neural circuits and hormonal systems. In many ways, predation is more appropriately interpreted as a form of food-getting behavior motivated by hunger and mediated by the seeking system (Panksepp, 1998).

CLASSIFYING AGGRESSION: MOTIVATIONAL CONSIDERATIONS

Significant debate surrounds the question of how to organize and classify the dog's aggressive behavior into functionally discrete and logically coherent categories. Most trainers and counselors have adopted some variation of Moyer's classification system (Moyer, 1968, 1971; Hart, 1980; Borchelt and Voith, 1982; Borchelt, 1983; Beaver, 1983)—a system that has resulted in a great deal of confusion and misunderstanding (see below). Other authorities have argued with varying degrees of cogency for a more simple classification system. O'Farrell (1986), for instance, has proposed a bipartite system, suggesting that canine aggression can be divided into two broad functional categories: dominance aggression and predatory behavior. This scheme places fear-elicited aggression under the same heading with dominance aggression: "'Fear-biting' is commonly distinguished from dominance aggression, possibly because it is felt to be understandable and excusable in a way that dominance aggression is not. It is, however, a variant of dominance aggression" (94). Although simplicity is often desirable, this arrangement is not very edifying or useful when one considers the numerous motivational assumptions it takes for granted and the equally numerous distinctions that it blurs for the sake of Ockham's razor. Further, the scheme stretches the concept of *dominance* in a way that further obscures its meaning and usefulness.

Since it is not clear how fear-related aggression might be used to enhance social status, O'Farrell's position would be made more appealing and defensible if she explicitly replaced the term *dominance* with the term *control related.* However, although such a revision would help to reduce some potential confusion in her scheme, the change would only open up another criticism. Reducing aggressive behavior to a control-related motivation still begs the question with respect to the special attributes of aggression that distinguish it from other control-related activities. Presumably, all voluntary behavior is control-related behavior, but not all voluntary behavior is aggressive, except, perhaps, in a philosophical sense. Furthermore, although many forms of aggression appear to be purposive and control related, some forms of aggression appear to occur as reflexive actions in response to specific triggers. Also, defining aggression as a control-related activity tends to obscure the unique motivational and situational factors differentiating aggression into varied species-typical forms—even predatory aggression logically collapses into a control-related category. Broadly speaking, both affective aggression and predatory behavior are control-related activities, but they are significantly different in terms of functional pur-

pose, evolutionary history, and neurobiological origins [see *Neurobiology of Aggression (Hypothalamus)* in Volume 1, Chapter 3]. The most persuasive reason for adopting the concept of control-related aggression is that it conceptualizes offensive and defensive aggression in terms that are functionally compatible with the instrumental learning paradigm—learning concerned with establishing control over the environment. On the other hand, the underlying motivational factors (e.g., irritability, frustration, or fear) differentiating aggression into different forms represent the preparatory establishing operations facilitating the expression and potential reinforcement of control-related aggression. These emotional unitary reactions (conditioned and unconditioned reflexes) are under the influence of classical conditioning. In combination, instrumental control efforts and emotional unitary reactions converge on situations having species-typical significance for the dog, whereupon the specific intention of aggression is revealed (e.g., territory related, possession related, dominance related, or fear related).

Avoidance Learning and Aggression

Tortora (1983, 1984) has also suggested an alternative scheme for categorizing aggressive behavior. He interprets the development of aggression in terms of avoidance learning, arguing that what many dog behavior consultants refer to as dominance aggression is better understood as *avoidance-motivated aggression* (AMA). Social aggressors may not necessarily be dominant; instead, they may merely be incompetent and unable to respond appropriately under social pressure. Tortora argues that aggressive dogs appear to lack a repertoire of confident skills with which to cope and manage everyday challenges and stressors:

> The data suggest that the initial source of the aggressive avoidance response was one or more forms of elicited aggression such as species-typical aggressive reactions to pain, frustration, discomfort, territorial intrusion, or threats to dominance. Furthermore, it appears that these aggressive responses were exacerbated by trauma or punishment. Finally, the universal lack of behavioral control over these dogs implies that they had few operant alternatives to gain reinforcement by compliance. From the case histories, it seems that these dogs were channeled down a path that allowed their initial innate aggressiveness to come under the control of the negatively reinforcing contingencies in the environment.
>
> The dogs in this study initially behaved as if they "expected" aversive events and that the only way to prevent these events was through aggression. The consequent reaction of the victim and the family, that is, withdrawal, turmoil, and belated punishment, confirmed the dog's "expectations" and reinforced the aggression. This positive feedback loop produced progressive escalation of the aggressive response, and the avoidance nature of the aggression presumably retarded or prevented its extinction. (1983:209)

The treatment program developed by Tortora is essentially a course of obedience training using various procedures, including remote shock, to enhance confidence and social competence. The operative assumption is that dogs exhibiting avoidance-motivated aggression need to learn systematically that they can *safely* control threatening or aversive events without resorting to aggression.

A strength of Tortora's functional analysis is that it rests on a strong body of supporting experimental research (Azrin et al., 1967; Hutchinson et al., 1971). In addition to being elicited by a variety of natural or learned triggers acquired through classical conditioning, aggressive behavior functions motivationally and behaviorally in a variety of ways, such as providing instrumental control over the physical and social environment. Animals can learn to avoid aversive stimulation by responding aggressively and may even learn and perform arbitrary instrumental responses to obtain an opportunity to attack a target provided as a reward (Azrin et al., 1965). The avoidance paradigm also offers an explanation for the persistence of some forms of aggressive behavior, since avoidance learning is marked by a strong tendency to persist over time and resist extinction (see *Fear and Conditioning* in Chapter 3).

Tortora does not reject the notion of elicited aggression (e.g., irritable, territorial, or dominance related), but stresses that the dog's repertoire of species-typical aggressive behavior and controlling natural triggers only represents part of the picture. Although aggression

may be originally elicited by a *natural* trigger, it can subsequently come under the control of conditioned stimuli or *learned* triggers through avoidance learning. In fact, dominant-aggressive dogs frequently do exhibit behavior that appears to be influenced by avoidance learning. A common and often confusing characteristic of dominance aggression is the absence of an adequate trigger to explain the ferocity of the attack. In other words, the magnitude of dominance attacks is frequently far in excess to what one might expect to occur under the operative circumstances present at the time. Such attacks often appear to occur under minimal or no provocation at all. Low-threshold or unprovoked attacks may be explained along the lines of avoidance conditioning, whereby neutral stimuli present at the time of attack may become conditioned or learned triggers via association with unconditioned or natural triggers. As a result, these conditioned triggers may become capable of eliciting aggressive behavior in the absence of natural triggers. In other words, aggressors may learn to anticipate aversive arousal (frustrative, irritable, painful) by association with other stimuli present at the time when aversive arousal led to aggression. As a result, such stimuli may gradually become discriminative signals controlling avoidance-motivated aggression. According to this general account, most aggressive behavior is learned as a means to anticipate and avoid actual or perceived threats, especially threats occurring under circumstances where other means of control are unavailable or ineffectual. Bottom line, according the AMA hypothesis, *dominance* aggression toward human targets appears to be more about *defensive* control than *offensive* status-seeking efforts.

Many attack situations involving defensive aggression (that is, aggression influenced by a component of fear or avoidance) appear to present characteristics consistent with Tortora's AMA hypothesis; however, attacks motivated by anger do not appear to involve an underlying component of fear. The offensive aggressor may exhibit threatening postures and gestures (standing tall and stiff, ears up and turned forward, tail held erect, lips forming an agonistic pucker), behavioral signs indicating confident aggressive arousal—not preparatory fear. The offensive aggressor may learn that threats and attacks serve to secure or protect vital interests and resources. For example, a dog that has learned to threaten and displace its owner in the presence of food may learn through positive reinforcement (that is, the continued possession of food) that such behavior works. Determining whether the particular behavior is under the control of positive or negative reinforcement depends on whether the behavior functions to terminate or avoid stimulation or serves to obtain or perpetuate stimulation. When aggression occurs while the dog is sleeping, resting, or eating, the attack may be analyzed in terms of the perpetuation of these activities or resources, that is, understood by appealing to positive reinforcement. On the other hand, such attacks may also be analyzed in terms of negative reinforcement, especially if the behavior is primarily motivated to terminate the presence of a threat, a source of irritation, or frustration. In general, the determination of whether aggression is defensive (avoidance motivated) or offensive depends on the presence of behavioral signs at the time of attack. However, distinguishing between these two forms of aggression on the basis of postural signs of fear may become progressively difficult in the case of the experienced avoidance-motivated aggressors, who may not exhibit any signs of overt fear, especially as they become progressively confident and sure about the likelihood of success. In general, though, whether defensive or offensive, aggressive behavior aims at establishing control over some intruding target. The notions of positive and negative reinforcement may actually obfuscate the vital concern; that is, aggression is reinforced by the control it succeeds to establish, regardless of the motivational substrate operative at the moment of attack (see *A Brief Critique of Traditional Learning Theory* in Volume 1, Chapter 7*)*. According to this perspective, punishment occurs when the aggressive threat or attack fails to avoid or terminate an aversive-thwarting situation or when it fails to obtain or perpetuate some gratifying activity or resource. These considerations are of vital importance for the effective control and management of aggressive behavior.

Social Dominance and Aggression

One of the most well-studied areas in ethology is aggression, especially aggression exhibited with the apparent purpose of establishing or defending social status or rank (Scott, 1992). The most widely adopted conceptualization of dominance aggression incorporates several interactive components, including an ethological dominance concept, species-typical signalization (gestures and postures signaling agonistic intent and rank—dominance and submission), early socialization, and learning. Dogs and humans both socially organize themselves by rank order (often involving very complex alignments) within a dominance hierarchy. Such organization is accomplished by various means, including the utilization of species-typical gestures and body postures employed to advertise and ritually defend the individual's status against challenges presented by others belonging to the same group. Sometimes, communication breaks down as the result of a misunderstanding or an outright power struggle, giving rise to conflicts and challenges that may escalate into overt attacks and fighting. The role of social dominance in the expression of aggression is examined in detail in *Social Dominance and Aggression* in Chapter 8.

Fear and Aggression

Normally, fear significantly inhibits aggressive behavior and causes the animal to freeze or flee—if it can. A fearful dog usually makes frantic efforts to escape when it feels threatened or is attacked. It is only under circumstances in which escape or appeasement is thwarted that a fearful dog may resort to aggression. First and foremost, the goal of fearful behavior is to escape or control threatening stimulation, with counterthreats and aggression emitted as a last resort. Fear aggression is always a defensive strategy and is most likely to occur when other means of escape or avoidance are thwarted. However, in cases in which fear aggression succeeds, the defensive threat or attack may undergo reinforcement and, under similar circumstances in the future, the behavior may be triggered by conditioned stimuli associated with the original eliciting situation. As already discussed, the result is the development avoidance-motivated aggression—behavior that may closely parallel dominance aggression but remains essentially defensive rather than offensive. Fear aggressors can be distinguished from dominance aggressors by the exhibition of defensive postures indicative of fear (e.g., ears back, tail tucked under the body, nervous snarling, and showing of teeth) and approach-avoidance conflict. In addition, the fear aggressor may engage in barking (a possible repetitive conflict behavior) and other signs of fearful arousal (licking movements) and agitation that occur when it is exposed to eliciting stimuli, such as a doorbell, the approach of a stranger, noisy children, skaters and other similar stimulation, or the approach of other dogs. Typically, the fear aggressor is most likely to threaten or bite when it is suddenly approached by a fear-eliciting person or dog, where escape is preempted (Borchelt, 1983). Once fear aggression has graduated into avoidance aggression, many of the telltale signs of fear may be replaced with increased confidence and reduced latency and occur under minimal provocation.

Fear-related or defensive aggression stands opposite to dominance-related or offensive aggression on the agonistic continuum. Whereas dominance aggression occurs most often in situations involving competitive conflict between conspecifics, stimulated by the coactive influences of frustration, irritability, and anger, defensive aggression is most often directed toward another group member or species, under the influence of acute threat, fear, or anxiety. The tendency to bite out of fear is most commonly seen among shy or nervous dogs that have learned to rely on biting as means of self-defense. Paradoxically, fear-related aggression and dominance aggression sometimes present together in the same dog. The term *bipolar aggression* is a good descriptive term for this condition, since opposing ends of the agonistic continuum appear to be alternately involved, depending on the situation.

Since fear-related aggression depends on the presence of fear for its expression, an important initial step in the counseling process is to make an exhaustive inventory of

the evoking stimuli and situations where aggression has occurred in the past. Detailed information should be gathered concerning the location, magnitude, and type (superficial, puncture, laceration, etc.) of the bites involved. Further, the originating causes of fear and aggression should be fleshed out and clarified. This is not always practical or possible, but an effort should be attempted in every case since the results are often very useful in terms of accurately describing the problem, prognosticating the likely outcome and benefit of training, and helping owners to understand their dog's problem. Fear-related aggression appears to be strongly influenced by predisposing genetic factors. Thorne (1944), for example, found that a single "fear-biting" Basset hound had a tremendous influence on a large group of descendants in terms of their relative fearfulness and reactivity. Of 59 dogs related to this highly reproductive female, 43 (73%) were shy and unfriendly. In addition to genetic predisposition, most etiological profiles show significant causality in terms of early socialization and exposure deficits or the contribution of learning. It is not uncommon to find cases involving all three factors. Voith and Borchelt (1996) suggest that excessive punitive interaction with puppies during house training may play a significant predisposing role in the development of fear-related aggression problems in adult dogs.

Distinguishing the effects of learning from other potential causes of fear is assisted by obtaining a behavioral history and performing a detailed evaluation. Dogs that are affected by a genetic predisposition are distinguished by a chronic, lifelong, and generalized fearfulness. They often suffer heightened or extreme sensitivity to sensory input and overreact in situations involving novel stimuli (neophobia), strangers, or unfamiliar animals. Differentiating cases exhibiting a genetic predisposition from those involving a socialization deficit is not always easy, since undersocialized dogs frequently exhibit similar signs and tendencies as genetically affected individuals. Temperament information about a dog's sire and dam could be helpful in making such determinations. Puppies isolated until week 14, or in cases where they come into the home at an unusually late date from an unknown situation, should be suspected prima facie as suffering a socialization problem. A lack of proper socialization and inadequate or traumatic environmental exposure occurring early in development are commonly associated with adult dogs' reactive fear toward strangers (xenophobia), fear of children (pedophobia), or fear of outdoors and new places (agoraphobia). In cases where fearfulness is the result of learning (e.g., startle, trauma, or abuse), a dog's reactions are usually limited to a more specific range of eliciting stimuli and situations. Of the three aforementioned etiologies, fearfulness stemming from past learning events is usually the most responsive to remedial training, with problems involving a genetic predisposition being the most difficult to work through in my experience. Fear biting suspected of being predominantly under the control of an underlying genetic causation should be carefully assessed and the owner informed of the limited benefits to be expected from behavior modification before proceeding. Although such dogs *may* respond to behavioral intervention, the goals of training should be discussed in terms of amelioration and management—not cure.

Obviously, reducing fearfulness is central to effective behavioral control and modification of fear-related aggression. Several methods have been employed for this purpose with varying degrees of success. The most beneficial techniques involve some combination of graded interactive exposure, counterconditioning, relaxation training, modeling, and response prevention. The most important consideration recommending the use of such procedures is that they help to facilitate the disconfirmation of a dog's adverse expectations of social contact while at the same time encouraging a more affirmative set of expectancies and interactive behaviors.

Cognition and Aggression

Dogs appear to form various prediction-control expectancies about future events based on the accumulation of information extracted from past experiences (see *Prediction-Control Expectancies and Adaptation* in Volume 1, Chapter 7). In general, these expectancies help

to promote a more secure existence by coordinating a dog's behavior relative to the most probable, although not yet actual (certain), circumstances. Prediction-control expectancies are continually undergoing appraisal and modification in order to most accurately fit or *adapt* a dog's behavior to the environment. These expectancies are influenced by emotional concomitants of success (elation) or failure (disappointment). In cases in which a high degree of correspondence exists between what a dog expects to occur and what actually occurs, effects of well-being and confidence prevail; whereas, under opposite circumstances in which their is little correspondence between what the dog expects to occur and what actually occurs, effects of depression and helplessness may ensue. Expectancies are adjusted in accordance with the occurrence of satisfying or distressful emotional concomitants resulting from the confirmation or disconfirmation of expectant arousal or action. For example, when a prediction expectancy is disconfirmed or proves inadequate, then *anxiety* ensues. On the other hand, when a control expectancy is disconfirmed or proves inadequate, then *frustration* ensues. These emotional concomitants of expectancy disconfirmation promote adaptive optimization through the activation of increased sensory vigilance and behavioral invigoration. Adaptive change is mediated through learning, and learning is guided by the affects of anxiety and frustration, resulting from the disconfirmation of prediction-control expectancies. Theoretically, when prediction-control expectancies are fully matched and coordinated with the environment, utopic adaptation is achieved, and further learning is unnecessary and does not occur. Under ordinary circumstances, anxiety and frustration promote learning and adaptive optimization of environmental resources. However, under conditions in which the environment is both highly unpredictable and uncontrollable, then pathological disorganization (learned helplessness) and behavioral disorder (impulsive-compulsive behavior) are prone to follow. In other words, a small amount of anxiety and frustration promotes adaptive success, whereas high levels of anxiety and frustration disturb learning and disrupt behavioral adaptation.

Preparatory arousal, attention, intention, and functional behavior are guided by prediction-control expectancies. Under ordinary circumstances, dogs select courses of action based on cognitive expectancies, unless the particular expectancy has been disconfirmed or the environment provides inadequate information with which to form adequate prediction-control expectancies. Under such circumstances, dogs may depend more on direct sensory information, until a more adequate expectancy is formed. This shift from expectancies to reliance on sensory information may be highly disruptive and stressful. In addition to resorting to sensory information, dogs may also be more inclined to rely on instinctive or species-typical impulses to secure the environment. Under highly threatening social situations which violate a dog's prediction-control expectancies (e.g., *trust*), increased sensory vigilance and behavioral invigoration may facilitate intense aggressive arousal and significantly lower thresholds for aggressive behavior. Unfortunately, as a result, the dog may modify prediction-control expectancies so that, under similar circumstances in the future, it may learn to preemptively prepare and respond aggressively under minimal stimulation and continue doing so until the operative expectancy is disconfirmed.

Although prediction-control expectancies may accurately reflect reality, under the influence of adverse learning dogs may form faulty expectations that may not adequately represent actual circumstances. This risk is particularly problematical in the case of escape and avoidance learning, in which case the avoidance response may preemptively interfere with a dog learning that the response is no longer necessary to control the anticipated threat (see *A Cognitive Theory of Avoidance Learning* in Volume 1, Chapter 8). For avoidance to discontinue, the operative prediction-control expectancy guiding the behavior must be first disconfirmed (e.g., via graduated interactive exposure and response prevention) and replaced with an alternative expectancy more adequately fitted to the actual situation. In addition to forming specific expectancies, dogs also appear to appraise and interpret events in very subtle ways that predispose them to preferentially engage in certain

behaviors rather than others. Cognitive appraisal assists dogs in modulating their moment-to-moment arousal levels as well as finely regulating appropriate actions to achieve a more subtle behavioral adaptation to the environment. These interpretive cognitive functions are especially evident in the case of complex social circumstances requiring a high degree of communication and cooperation, such as play. In the case of play, aggressive elements and sequences are interpreted in terms of the play partner's intention and various play metasignals confirming that the interaction is *just play.* Interpretive appraisal of the social intention of others provides the basis of communication. The mutual communication of intent determines whether competitive or cooperative behavior will ensue between interactants. Communication of intent may not only predict aggressive or affiliative action, it may also define the most likely outcome of the encounter. A highly motivated dog (e.g., starving) may show a very strong intent to defend a bowl of food, sufficient to cause a less hungry potential competitor to withdraw—even though under other circumstances the competitor may be dominant and the aggressor submissive. The way a dog interprets the intention of interaction strongly influences how it will respond to it. Petting or hugging coming from one person may be welcomed and reciprocated with expressions of shared affection, whereas the same actions coming from another person may be interpreted as a threat and, perhaps, evoke an aggressive response. Such interpretations of intent are strongly influenced by the quality of attachment and communication between the human and the dog. Interpretive appraisal of social intention under the influence of high levels of affection, familiarity, and trust appears to promote strong and durable inhibitory effects over aggression between closely bonded interactants.

Another important cognitive influence over aggressive behavior is cost-benefit assessment and risk taking. Engaging in aggressive conflict brings with it considerable risk. Cost-benefit assessment appears to play a significant role in the case of offensive aggression, where the goal is to achieve some benefit or resource. In the case of a starving dog, the risk of injury that may result from fighting is offset by the benefit of eating. In situations where the potential cost of behaving aggressively (loss or injury) exceeds what might be conceivably gained by the action, a dog is more likely to steer away from initiating an aggressive conflict. Aggression is most likely to occur in motivationally significant situations, where the risks of aggression are minimal (costs) and the potential benefits are substantial. Finally, dominant dogs appear to be more inclined to engage in risk-taking behavior, whereas submissive dogs may be more conservative and careful regarding risky behavior. A predisposition to take risks may be a genetically expressed trait that is more characteristic of dominant individuals than submissive ones. Submissive individuals may be genetically prone to avoid risk taking, unless the perception of risk is motivationally offset by a pressing biological need or threat and the potential benefit of success is sufficiently enticing.

A potential factor altering risk assessment abilities is stress. Quatermain and colleagues (1996) have found that stressed mice more rapidly engage in risk-taking behavior than unstressed controls. In the case of dogs, stress may lower thresholds for aggressive risk taking, causing otherwise submissive and compliant dogs to become periodically more irritable and aggressive. Stress appears to impair normal attention and memory functions (Mendl, 1999) and cortical impulse control over subcortical activity (Arnsten, 1998), potentially lowering behavioral thresholds for aggression or liberating species-typical offensive and defensive behavior in response to wrongly interpreted social signals. The systematic reduction of stress is an important aspect of effective behavior therapy. Such treatment efforts may facilitate risk-assessment normalization and improve other cognitive functions involved in the modulation of aggressive arousal and the regulatory control of aggressive behavior. A neural site of particular interest in this regard is the amygdala (see *Limbic System* in Volume 1, Chapter 3), which appears to serve a central role in social communication by mediating direct eye contact,

by interpreting socially significant facial expressions, and by assessing the interactants emotional disposition and intent (Allman and Brothers, 1994). Under the dysfunctional influence of excessive stress, the intent of social signals may be distorted and misinterpreted, causing a dog to respond with inappropriate fear or aggression. The amygdala may play a particularly prominent role in the case of dominance-related aggression (Fonberg, 1988).

A Nomenclature of Aggressive Behavior

Functionally speaking, aggressive behavior, not stemming from idiopathic or pathological causes, can be viewed as an adaptive effort to establish control over some vital resource or situation that cannot be effectively controlled through other means. A variety of motivational and functional factors are presumed to influence the expression of aggressive behavior in dogs (Table 6.1). Obviously, these types of aggression exhibit a great deal of functional overlap. Although useful as a descriptive inventory, the list fails to provide a consistent functional framework for analyzing aggressive behavior. Instead, like other similar lists in the dog behavior literature, it brings together various forms of aggression under the discordant rubric of species-typical elicitors, physiological causes, and functional purposes. As a classification system, such discordance precludes productive analysis and the extraction of general principles.

Moyer (1968) has devised a classification system that is based primarily on stimuli or situational conditions that regularly evoke aggression (Table 6.2). Moyer's inventory of stimulus situations evocative of aggression ends up including general physiological and psychological influences as part of the evocative situation. The inclusion of instrumental learning is particularly confusing and discordant in the framework of the system's stated purpose. Instrumental learning may certainly influence a dog's propensity to bite, but such learning is not part of the evoking situation, at least not in the same sense, for example, as an intruder is part of a situation that evokes territorial aggression. Instrumental learning does not logically belong to the list, especially if other forms of learning such as classical conditioning are excluded as situational influences—an exclusion that makes very little sense, given the inclusion of instrumental learning. But, most importantly, Moyer's taxonomy chiefly fails because it does not properly emphasize the very active and purposive character of aggressive behavior. Aggression is not just passively evoked by an adequate stimulus situation or physiological state. On the contrary, most often, aggressive behavior is guided by an intention to actively control or change the environment somehow, especially those parts of the environment that otherwise resist control or *bite* back.

Moyer's decision to include instrumental learning in his list of evocative situations underscores the vital role that learning plays in the acquisition and expression of aggressive behavior. Aggression is not merely a passive response to circumstances—it is more often an active and purposive effort aimed at obtaining various ends through the assertion of threats or attack. As such, aggression can be adequately understood and controlled only by recognizing that it is motivated and emitted under the influence of both emotional (reflexive) and purposive (instrumental) components. Functional aggressive behavior depends on the presence of significant setting events (broad contextual and motivational variables), transient emotional *establishing operations* (e.g., frustration, irritability, and anxiety), and an evocative target or situation toward which the threat or attack is directed. *The goal of aggression is control.* In effect, Moyer's taxonomy is an incomplete list of setting events, establishing operations, and targets under whose influence aggression is most likely to occur and *potentially result in reinforcement*—that is, result in enhanced control over the environment.

Although some forms of environmental stimulation may at times elicit *reflexive* attack (rage), such behavior is rather rare in comparison to the incidence of functionally integrated and purposive aggression. Aggression is often aimed at controlling the behavioral trajectory of another whose interests or

Table 6.1. Descriptive and functional characteristics of aggression

Behavior	Etiological factors	Description-function
Avoidance-motivated: Often socially insecure and incompetent.	Fear Anxiety Control Learning Socialization	Occurs in situations where the dog has learned that aggression successfully postpones or avoids an aversive stimulus or situation.
Control (dominance)-related: Dogs often lack appropriate boundaries and social inhibitions. Often limited to family members. Occurs around defended areas (e.g., bed, doorways, furniture) or items. Most often observed in male dogs.	Frustration Anxiety Learning Hormonal Genetics Socialization	Aggressive behavior occurring under a variety of situations involving competition and control. Dominance aggression generates social distance and establishes hiearchical stratification or status between socially familar competitors.
Dysfunctional: Explosive behavior may be related to PTSD (see *Low threshold*).	Frustration Anxiety Helplessness Learning Socialization	Occurring under inappropriate stimulus conditions and vastly exaggerated (disproportionate) within the context. Frequently, observed in cases involving dominance aggression.
Fear related: Attacks associated with postural signs of fear (e.g., lowered posture, tail down, ears back).	Fear Anxiety Helplessness Genetics Learning Socialization	Occurs only as a last resort when escape from an intensely fearful situation is not otherwise possible. Fear-related aggression is employed to escape but not to otherwise control or change the situation.
Idiopathic: May involve epilepsy.	Neurologicial Pathology Genetics	Aggression occurring as the result of unknown causes (see Pathophysiological).
Instrumental: Most forms of aggression are affected by learning.	Pain Anxiety Fear Frustration	Aggression enhanced or acquired through classical or instrumental learning but not specific to any single stimulus situation.
Intermale/interfemale: Aggression between females is most often seen among dogs sharing the same residence. Appears with sexual and social maturity.	Fear Dominance Hormonal Genetics Learning Socialization	Provoked by the close proximity of conspecifics of the same sex. Occasionally, dogs will fight with members of the opposite sex, but this is much less common.

TABLE 6.1. Descriptive and functional characteristics of aggression—*Continued*

Behavior	Etiological factors	Description-function
Irritable: Results from painful stimulation associated with injury, various grooming and veterinary procedures.	Pain Fear Frustration Pathology Genetics	Associated with situations involving cumulative stress: crowding, frustration, punishment, pain, and deprivation. Includes threats, biting, and scratching to escape painful stimulation.
Low threshold: Aggressive behavior occurring with little or no apparent provocation or warning. Commonly associated with dominance aggression and so-called springer rage syndrome.	Frustration Anxiety Neurological Helplessness Learning Socialization	A form of dysfunctional agression occurring in cases where normal inhibtions and central control over aggressive behavior is compromised—sometimes referred to as episodic dyscontrol syndrome.
Maternal: May be directed toward inanimate objects when pseudopregnancy is present.	Hormonal Genetics	Occurs when the nesting area or young are approached. Most often directed toward strangers.
Pathophysiological: If should be considered especially in the cases of aggressive behavior with an acute onset and presenting under poorly defined triggers.	Hormonal Genetics Pathology	Results from various underlying physical causes from hypothyroidism (Reinhard, 1978; Dodd, 1992; Dodman and Mertens, 1995) to various neurological disorders (neurogenic) such as epilepsy (Holliday et al., 1970). The role of hypothyroidism in aggressive behavior remains controversial (Polsky, 1993).
Playful: May be directed toward the owner as a nuisance. Excessive mouthing and biting on hands and clothing.	Competition Learning Socialization	Noninjurious aggressive displays during playful encounters, including stalking, pouncing, bumping, gentle biting, and pawing.

(*continued*)

TABLE 6.1. Descriptive and functional characteristics of aggression—*Continued*

Behavior	Etiological factors	Description-function
Possessive: Although commonly associated with dominance-related aggression, it may also occur independently. Appears in puppyhood and thoughout the life cycle.	Frustration Anxiety Learning Socialization	A form of aggression provoked by competition over a possession like a toy or food item.
Predatory: Distinguished from other forms of aggression by the absensce of affective arousal.	Learning Genetics Socialization	Attack released by the presence of prey animals or preylike stimulation. Most often triggered by fleeing movement.
Protective:	Fear Anxiety Learning Genetics Training	Agression emitted in the context of a socially significant other that would not likely occur otherwise.
Redirected: Commonly observed when an owner attempts to break up a dog fight.	Fear Frustration Anxiety Socialization Pain	Threat or attack that occurs when agression is blocked toward a preferred target and directed instead toward a more immediately available one.
Territorial defense:	Fear Anxiety Control Learning Training	Aggression that is directed toward a target intruding on an established territory.
Trained:	Frustration Anxiety Control Learning Play	Aggressive behavior that has been systematically agitated and brought under the control of specific releasing and inhibitory cues (e.g., protection-dog training).
Xenopic: See *Fear-related aggression*.	Fear Anxiety Genetics Learning Socialization	Agression that is directed toward strangers regardless of situation or territorial priority.

TABLE 6.2. Moyer's taxonomy of aggressive behavior

Predatory: evoked by a prey animal.
Intermale: evoked by the presence of a strange male conspecific.
Fear induced: preceded by efforts to escape a threatening situation.
Irritable: evoked by pain, frustration, deprivation, and other stressors and directed toward either animate or inanimate targets.
Territorial: evoked by an intruder entering an established territory.
Maternal: evoked by an intruder perceived as a threat by a mother to her young.
Sex related: evoked by the same behavior that elicits sexual behavior.
Instrumental: enhancement of any of the above through learning.

intentions conflict or collide with the aggressor's interests or intentions (see *Control-seeking Vector Analysis of Territory* in Chapter 7). Control-related aggression denotes any threat or attack aimed at controlling another animal or person, especially in response to social challenges and conflicts or intrusive threats on territory. Finally, control-related aggression is typically employed under adverse conditions (involving heightened frustration, anxiety, or irritability) to control social prerogatives, biological imperatives, or territorial space (any area defended by the dog). Dogs exhibiting aggressive behavior typically do so to secure or defend some vital resource or place against unwanted intrusion or to counter a perceived or actual threat asserted by a rival.

Predatory Behavior

Moyer's inclusion of predatory attack as a form of aggression alongside fear-induced or irritable attack is questionable and potentially misleading. As previously mentioned, predatory behavior might best be treated under some independent category such as "killing for food." This seems appropriate, since predatory behavior is not primarily motivated by affective arousal (anger). In addition, predatory aggression or *quiet attack* typically occurs without signs of sympathetic arousal. In contrast, affective attack is distinguished by the presence of strong sympathetic arousal and anger. Predatory behavior appears to belong to a distinct behavioral and neurological system operating independently of affective aggression, perhaps involving the appetitive seeking system (Panksepp, 1998). An interesting neurobiological finding in this regard is the observation that the neurotransmitter norepinephrine inhibits predatory aggression while facilitating affective aggression like fighting (Siegel and Edinger, 1981). These findings (and many others like them) support the assumption that predatory aggression and affective aggression are mediated by very different biological and behavioral systems (see *Neurobiology of Aggression* [*Hypothalamus*] in Volume 1, Chapter 3). Although predation belongs to an independent motivational system, predatory behavior may be influenced by coactive anxious and frustrative influences that may ultimately lead to the expression of *affective aggression,* a possibility emphasized by Panksepp:

> Of course, this does not mean that the whole predatory attack sequence or any other real-life emotional pattern ever remains under the control of a single emotional system. A predator surely experiences irritability or frustration if the prey struggles so vigorously that it seems liable to escape. Thus, in real life, there are sudden shifts in emotions depending upon the success or failure of specific behavioral acts, as well as in the changing cognitive expectations and appraisals of each situation. (193)

None of the foregoing should be construed to imply that predatory aggression is innocuous or in any sense less dangerous than other forms of canine aggression. Predatory motivations have been implicated in several cases involving vicious maulings and deaths of humans by dog packs (Borchelt et al., 1983). In one of these cases, a large pack of eight dogs, with a known history of predatory behavior, attacked and killed a 14-year-old boy who was riding a motorcycle. Reportedly, the pack had been observed earlier attacking a deer that they had brought down but that managed to escape. This incident occurred approximately 1 hour prior to the attack on the boy. In another incident, a pack of dogs attacked an 11-year-old boy who survived severe injuries to report hearing the dogs "baying, as if chasing something" approximately 15 minutes before the attack. In both cases, there appears to have been a frustrated or redirected predatory motivation involved in the attacks, suggesting that some forms of "predation" are motivated by more than simple hunger and nonaffective neural circuitry. Another case involved a pack of several dogs that was kept by an elderly couple in rural Indiana (Figure 6.2). The dogs, which were permitted to run free, attacked a 10-year-old girl riding her bicycle near the couple's property. In an effort to escape the attack, the child ran into a nearby wooded area, where she was later found dead. The child received numerous wounds and parts of her flesh had been torn away and apparently eaten by the dogs (Borchelt et al., 1983). Winkler (1977) reviews the case histories of 11 fatal dog attacks and cites "threatening behavior or territorial invasion" as the most common causes, without mentioning the possible role of predation or a history of predatory behavior in the dogs involved. Although not mentioned specifically, several of the cases he describes are not entirely inconsistent with a predatory interpretation. Incidentally, of the nine cases where the sex of the dog was known, males accounted for seven of the attacks, with the remaining incidents involving a female and a male and female pair. These data suggest that male dogs may be at a significantly greater risk of delivering a fatal attack than are female dogs.

Genetics and Aggression

There appears to exist a strong heritable factor affecting the predisposition of dogs to behave aggressively. Numerous studies have identified a genetic influence affecting animal behavior in the opposing directions of increased fearful behavior, on the one hand, and increased aggression, on the other (see *Genetic Predisposition and Temperament* in Volume 1, Chapter 5). In general, domestication has exerted selective

Fig. 6.2. Under the influence of packing behavior, large groups of dogs can represent a serious predatory threat. These dogs were involved in a fatal attack on a young girl who was riding her bicycle near their home property. (Photo courtesy of V. L. Voith.)

pressure toward behavioral thresholds conducive to reduced fear and aggression, thereby making dogs more socially responsive and tamable by humans (Price, 1999). Although the general trend has been toward a reduction of fear and aggression, significant variations of excitability exist between breeds and individuals within these different breeds. With respect to aggression, some dog breeds appear, on the whole, to be more aggressive and reactive than others to emotionally provocative stimulation. Scott and Fuller (1965), for example, found clear differences in the aggressive behavior of different breeds emerging at an early age. Of the five breeds observed and tested, they found wirehaired fox terriers to be the most aggressive, basenjis and shelties somewhat less aggressive, and beagles and cocker spaniels much less aggressive. Hart and Hart (1985b) analyzed the cumulative opinions of 48 veterinarians and 48 obedience judges with respect to the ranking of 56 breeds according to 13 behavioral traits. They found that the surveyed professionals shared significant uniformity in their assessment of various traits, enabling the authors to perform a cluster analysis for the various breeds represented in terms of such things as their relative aggressiveness, trainability, and reactivity. Their results show some conformity with Scott and Fuller's earlier findings. For example, the fox terrier is included in the cluster characterized by "very high aggression, high reactivity, medium trainability," whereas beagles and cocker spaniels are included together under the cluster "high reactivity, low trainability, medium aggression." Although such statistical studies as the above represent a good starting point, the results are difficult to generalize because they are limited to personal opinions about behavior—not objective assessments. Even the opinions of professionals are subject to considerable individual and cultural bias. In other words, the study tells us more about how veterinarians and obedience judges feel about the behavior of various breeds than it tells us about the actual behavior of the breeds specified. To make the results reliable with respect to dog breeds, they must be validated by comparison with more objective assessment tests and experimental observations of breed differences, such as provided by Scott and Fuller's work.

A putative heritable factor in the expression of dominance-related aggression has been identified in the English springer spaniel (ESS). As the result of a random national survey of ESS owners, Reisner (1997) found what appears to be a significant breed disposition toward developing dominance-related aggression. She reported that 26% of the ESS had bitten someone, with 65% of those persons bitten being family members or people with whom the dog was familiar. In addition, 48% of the dogs had growled at, snapped at, or bitten family members in a dominance-related context. Finally, the tendency to exhibit dominance aggression was associated with dogs coming from one particular kennel, suggesting the possibility of a popular sire effect. The influence of breed predisposition is apparent in some epidemiological studies of reported dog bites (Wright, 1991). Although mixed breeds are most often implicated in biting incidents, representing between 41.1% and 47.4% of bites reported, some specific purebred dogs appear to represent a greater risk than others. For example, Gershman and colleagues reported that German shepherds and chow chows were most likely to bite nonhousehold members, victims who were often children. It should be emphasized, however, that interpreting breed-related bite statistics is fraught with difficulties (Lockwood, 1995), not the least of which is breed identification. Many dogs may be misidentified and lumped together under a particular breed. Also, as Wright points out, statistical bite rates relative to breed must be carefully weighted against the numbers of a particular breed living in the geographical area from which the sample is derived—a requirement that is not usually satisfied by statistical analyses comparing dog bite rates by breed.

Hormones and Aggressive Behavior

Increased competitiveness and aggressive behavior are often associated with hormonal changes occurring around puberty, a biological change that may lower the threshold for several significant sex-related behavior patterns, including intermale and interfemale aggression. While lowering the threshold for

general activity, urine marking, and aggressive behavior, the threshold for pain and fear may be elevated under the influence of these various hormones.

Stress Hormones and Aggression

The effects of endogenous hormones on aggressive behavior are evident in wild canids. A lower threshold for aggressive behavior is exhibited by both male and female wolves during the annual mating season, when both sexes show an increased tendency to engage in sex-related aggressive behavior (Derix et al., 1993). This sharp increase in aggressive behavior is probably mediated by a number of interacting hormonal systems. The alpha female can be particularly intolerant and hostile toward her female subordinates. McLeod et al. (1995) have shown that the upsurge of aggressive activity among captive wolves is especially stressful (by cortisol measures) on the lowest-ranking female and the second-ranking male.

Increased corticosteroid levels may play an indirect role in regulating sexual and competitive activity among wolves. Only the dominant female comes into full estrus and whelps young. Estrus in subordinate females is suppressed by some external cause, possibly as the result of the dominant female's continuous harassment and badgering before, during, and after the mating season. Estrus may be blocked by stress-mediated mechanisms involving corticosteroid secretions or related physiological mechanisms, such as stress-mediated suppression of luteinizing hormone (Sapolsky, 1990, 1994). In addition to impeding reproductive activity in subordinate females, stress produced by aggressive interaction between wolves appears to reduce the sex drive of subordinate males, as well. Consequently, the increase of aggressive interaction during the mating season may serve to "disable" rivals sexually and competitively, while helping to achieve an optimal physiological state for reproduction in the dominant or alpha pair.

It is interesting to note in this regard that Sapolsky (1990) found that dominant males among free-ranging olive baboons showed distinct differences in cortisol concentrations, depending on the presence or absence of five personality traits. Dominant baboons were most likely to have optimally low cortisol concentrations, if (1) they were able to differentiate between threats and neutral interaction, (2) they initiated the fight with the threatening rival, (3) they won the fight they initiated, (4) they exhibited differentiated behavior after winning or losing a fight, and (5) they redirected aggression toward another baboon when they lost a fight. Dominant males not exhibiting these traits tended to have cortisol levels similar to those of subordinate males.

Sex Hormones: Estrogen, Testosterone, and Progesterone

Estrogen (estradiol) levels are highest during proestrus, with progesterone levels increasing as the female enters estrus. Progesterone appears to exercise a modulatory effect over estrogen, and only after estrogen levels begin to fall will the female become receptive toward the male. Also, as estrus is approached, circulating testosterone in female dogs reaches plasma levels that are comparable to those in male dogs (Olsen et al., 1984). The various sex hormones are closely related steroidal compounds, with testosterone being easily biosynthesized from progesterone and estradiol synthesized from testosterone (Johnson, 1998).

Estrogen affects dog behavior in many ways: it increases general activity levels, promotes increased urine output and marking, increases vocalization, and stimulates nervous arousal in female dogs (Hart, 1985). All of these changes are the result of estrogen's threshold-lowering effects on the female brain, especially involving target areas mediating the expression of proestrus sexual behavior needed to attract a mate. Progesterone, on the other hand, appears to exercise an opposite effect to that of estrogen by generally elevating behavioral thresholds and asserting a calming effect on dogs and enhancing their receptivity to intimate contact. In high doses, progesterone may even induce general anesthesia. Not all practitioners agree on the anti-aggression effects of progesterone. For example, Overall (1997) directly implicates progesterone as an aggression-facilitating hor-

mone, noting that "high levels of aggression in hamsters are associated with the presence of progesterone" (97). Although progesterone may facilitate certain forms of aggression under the influence of certain hormonal environments in certain species (Archer, 1988), the general contention that progesterone promotes aggressive behavior does not appear to be supported by the weight of experimental evidence (Kislak and Beach, 1955; Fraile et al., 1987) and the clinical impressions of many practitioners who use progesterone to control aggressive behavior in dogs. Several laboratory and clinical reports have noted the threshold-elevating effects of progesterone on aggression in both male (testosterone environment) and female (estrogen environment) animals, including intact dogs (Voith, 1980c; Joby et al., 1984) and other domestic species exhibiting undesirable aggressive behavior (Hart, 1985; Houpt, 1991). As of 1991, Houpt described the progestins as the "most effective pharmacological treatment of aggression now available" (66). Progestins in the form of megestrol acetate (Ovaban) or long-lasting injections of medroxyprogesterone (Depo-Provera) *were* frequently administered to control aggression in dogs. Unfortunately, progestins produce a number of potential side effects, including diabetes mellitus, mammary tumors, sterility in intact males, and excessive weight gain. Coupled with the growing popularity of psychotropics, the use of progestins has become much less common. In combination with appropriate behavior modification, however, progestin therapy remains a viable short-term adjunctive treatment for the control of some forms of intractable intermale aggression and other sexually dimorphic behavior problems (Hart and Eckstein, 1998).

Adult sensitivity to androgens and estrogens may be influenced by perinatal exposure to these sexual hormones. Simon and Whalen (1987) found that female mice treated with testosterone or estrogen on the day of birth exhibited an enhanced responsiveness to the hormone upon reaching adulthood. Testosterone-treated mice showed increased aggressiveness in response to testosterone but not to estrogen, whereas estrogen-treated mice selectively responded to estrogen but not to testosterone.

Male and female sexual hormones play an important regulatory role in the expression of sex-related intraspecific aggression. Whether such hormones play a significant role in the expression of interspecific aggression (e.g., toward people) remains an open question. Although testosterone has been often implicated as a facilitating hormone, its role in the expression of aggressive behavior is anything but clear and straightforward. Both androgens and estrogens appear to facilitate aggression, especially during the mating season. Perhaps the facilitative effects of sex hormones on aggression are mediated indirectly by the activation of sex-related emotions and drives, making aggression most likely to occur in the presence of species-typical triggers shown by conspecifics operating under the influence of similar hormonal changes.

Effects of Castration on Aggressive Behavior

The importance of sexual hormones for the modulation of aggressive behavior has long been recognized. However, the effect of hormones on dog behavior is ambiguous and highly variable. Endogenous sexual hormones appear to play a role in the development of some behavior problems (Borchelt, 1983; Wright and Nesselrote, 1987). The relationship between androgens and unwanted behavior is especially evident in the case of aggression, where male dogs present much more often than females—as much as 90% more often by some estimates (Voith and Borchelt, 1982). In general, males also present more frequently than females with other common behavior problems (Hart and Hart, 1985a), including playfulness, destructiveness, snapping at children, territorial defense, and general activity excesses. According to the Harts' study, females are more trainable, easier to house train, and more affectionate. Areas where no significant differences between the sexes were found include watchdog barking, nuisance barking, and general excitability. Voith and Borchelt (1996) reported similar findings indicating that male dogs present more frequently with behavior problems than females (Figure 6.3).

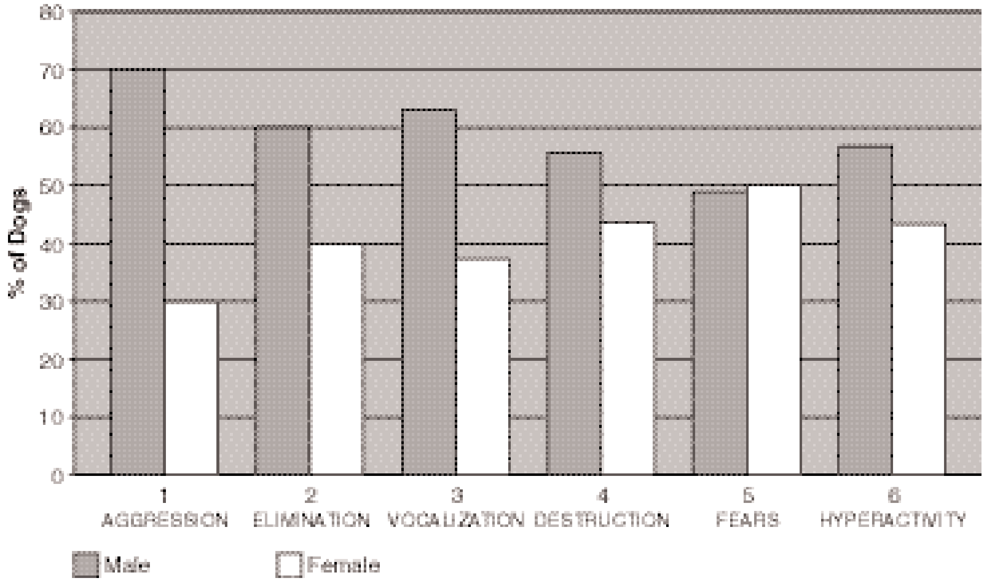

FIG. 6.3. Distribution of behavior problems by sex (N = 1718). Males tend to present more often with various common behavior complaints, which suggests the presence of a hormonal influence underlying the development of some behavior problems. From Voith and Borchelt (1996).

From such data, one might suppose that a more or less direct causal connection exists between the presence of male hormones and increased tendency to behave aggressively. However, such a robust causal relationship between hormones and aggression does not appear to exist. This lack of a definitive cause-effect relationship is evident in the highly variable effect of castration on behavior. Contrary to common belief, castration often fails to affect offensive and defensive aggression significantly; neither does it typically have a significant effect on a dog's general activity level. In general, castration appears to exert its strongest influence over sexually dimorphic behavior patterns, such as intermale aggression, urine marking, mounting, and roaming. Neilson and coworkers (1997) found that such behavior was reduced between 50% and 90% following castration.

Many studies have been performed to evaluate the effects of castration on male behavior. For instance, Beach (1970) carried out a series of experiments investigating the effects of castration on the sexual behavior of dogs. The dogs included in his study were experienced copulators. If testosterone predominantly controls or mediates the expression of copulatory behavior, then one would expect to observe a sharp decline in sexual activity in castrated dogs. However, Beach found that castration had limited effects, with no apparent effect on sexual response latency or mounting frequency in the dogs he observed over the study period, though he did find a reduced frequency of intromission and more brief durations of coital lock.

These findings are consistent with the effects observed after castration on other sexually dimorphic male behavior patterns like aggression, roaming, urinary scent marking, mounting, and intermale fighting. Although such behavior patterns are not always entirely eliminated by castration, their frequency and magnitude may be reduced—occasionally very significantly so. In the case of agonistic displays, one should expect a slight general modulation in the direction of reduction, especially in terms of the intensity/duration of episodes and the tendency for aggression to

escalate. Also, the denouement phase following an episode may be much more steep following castration than before. The effect of castration is one of degree and subtlety—an effect that is often unobserved and unappreciated by the owner.

Some hormonal factor probably exists in the etiology of dominance aggression, since males exhibit the behavior problem more often than females, but the cause and source of this effect may be largely independent of a dog's adult sexual status. The most likely mechanism for the effect of hormones on aggressive behavior is androgen-mediated perinatal differentiation of neural tissue. Early ontogenetic exposure to sex hormones may facilitate the elaboration of sexually dimorphic circuits modulating respective threshold differences between males and females for the display of aggressive behavior as adults.

If testosterone actually plays a significant role in the expression of aggression, one might reasonably expect to see increased signs of it between 6 to 8 months of age, when dogs undergo an endogenous surge of androgen activity (Hart, 1985). Although many dogs do appear to go through an *adolescent adjustment phase* around this period, it is not a statistically significant time frame for the expression of dominance-related aggression, although dogs may become more competitive and difficult and become more aggressive toward other male dogs. Tinbergen (1958/1969) describes some of these apparent and dramatic effects of the adolescent hormonal surge observed among free-ranging huskies in Greenland:

> We followed the behavior of two young males carefully and found, to our surprise, that when they were about eight months old they suddenly began to join their pack in fights with their neighbors. In the very same week their trespassing upon other territories became a thing of the past. And it was probably no coincidence that in that same week both made their first attempts to mate with a female in their own pack. (34)

Castration is often recommended as a means for controlling dominance-related and other forms of aggression (Borchelt and Voith, 1986). The most commonly cited study concerning the therapeutic efficacy of castration on behavior was performed by Hopkins and colleagues (1976) (Figure 6.4). Unfortunately, the study examined a very small sample of dogs (N = 42) and was poorly controlled. The authors noted striking improvement in dogs exhibiting various behavior problems, including roaming (16 dogs, 90% improved), mounting (15 dogs, 67% improved), intermale fighting (8 dogs, 62% improved), and urine scent marking (10 dogs, 50% improved). Both territorial aggression (8 dogs) and fear-related aggression (4 dogs) showed no improvement following castration: "The subjective reports of the present study substantiate the contentions by others that only aggressive behavior toward other males is altered by castration" (1110). One potential source of error in the study was the fact that most of the dogs (37 of 42) involved were castrated to curb an unwanted behavior problem in the first place, perhaps biasing the owners' observations to some extent in the direction of a placebo effect. The owners might have also picked up a few tips on how to control their dog's unwanted behavior, thereby confounding the results. Additional support for the putative benefits of castration on dominance-related aggression have been reported by Neilson and colleagues (1997), who found that 25% of dogs exhibiting aggression toward family members improved between 50% and 90% after castration.

Finally, testosterone appears to be released following competitive victories, whereas a decrease of circulating testosterone follows defeats (Kreutz et al., 1972). The differential increase or decrease of testosterone may affect the relative physical size (anabolic effect) of dominant and subordinate animals, lower aggression thresholds, and increase the magnitude of aggressive behavior. Increased testosterone levels may also provide a source of positive reinforcement for the successful combatant, perhaps promoting feelings of well-being and elation that occur as the result of the victory. Testosterone appears to facilitate aggressive arousal and preparatory reflexes conducive to agonistic success. For example, the direct stare and focused readiness commonly

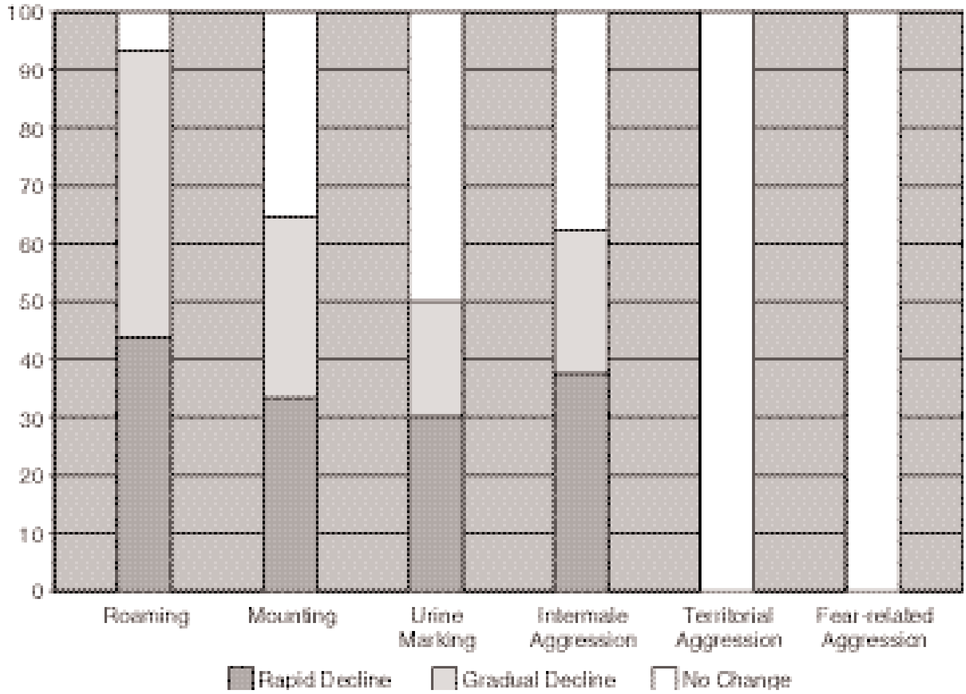

FIG. 6.4. Percentage of dogs exhibiting behavior changes involving various problems following castration. After Hopkins et al. (1976).

preceding dominance contests may be mediated by testosterone. Many studies involving a variety of species have shown that testosterone enhances selective attention in the direction of the target while simultaneously reducing distraction to extraneous stimuli (Archer, 1988). Attention control is a significant factor in the modification of such behavior. Once attention is frozen on the target, it is very difficult to disrupt or divert it, making it of utmost importance to capture the dog's attention during the earliest stages of aggressive arousal. In addition to possibly reducing the reward value of successful aggressive competition, castration may serve to reduce preparatory arousal and decrease the dog's ability to focus its attention fully on the target of attack, thereby making it more easy to divert or disrupt the dog's agonistic intentions and direct the dog into incompatible counterconditioning activities. Consequently, although castration alone may not eliminate aggression, it may make aggression problems more responsive to management and control efforts.

Effects of Prepubertal Castration on Behavior

Some veterinarians and humane groups have promoted early castration as a viable population and behavioral control measure, claiming that prepubertal castration produces superior effects over the current practice of performing castration and spay surgeries at 6 months of age. The evidence supporting this opinion is mixed and controversial. For example, on the pro side of the debate, Lieberman (1987) reports findings based on the results of a questionnaire generated by the Medford, Oregon, SPCA spay and neuter program. The study collected and compared information on about 400 dogs that had been castrated at different ages. The sample was divided into two groups: (1) 200 puppies castrated at 6 to 12 weeks of age, and (2) 200 puppies castrated after 6 months of age. According to Lieberman's survey, the male dog's unwanted sexual and aggressive behaviors were significantly reduced by prepubertal castration when

compared to the group of dogs castrated after 6 months of age. If valid, these findings contradict the observation by Hopkins and colleagues (1976) that the "age of the dog does not seem to have a pronounced influence on the effectiveness of the operation" (1110).

On the con side, Lieberman's findings have been challenged by a controlled study carried out by Salmeri and coworkers (1991), who found that puppies castrated at both 7 weeks and 7 months exhibited little positive difference in significant behavioral parameters (for example, barking, playfulness, aggression toward other dogs, affection toward people, and outgoing nature)—*all significant traits were unaffected by castration.* The only behavioral traits influenced by castration were excitability and general activity, but both in a direction opposite to what one might expect; that is, *dogs castrated early in life tended to become more excitable and active than intact controls.* Even in cases involving intermale fighting, few dogs exhibited significant improvement after castration, although the tendency to fight appears to have been modulated to some extent. Perhaps castrates are less attractive as aggressive opponents for intact males. Finally, Jagoe and Serpell (1988) question the effectiveness of prepubertal castration in 6- to 12-week-old puppies, arguing that the surgery may be detrimental to a dog's health, but they present no significant evidence to support their concern and warning. Although the scientific evidence is mixed, the selective use of early castration might be seriously considered in puppies exhibiting signs of excessive aggression at an early age.

Effects of Spaying on Female Aggressive Behavior

Voith and Borchelt (1982) reported observing a tendency of some female dogs to exhibit an increase in dominance-related aggressive behavior after spaying. The authors speculate that female dogs displaying such tendencies may have been exposed to fetal androgenization, resulting in their malelike behavioral characteristics (see *Perinatal Androgenization* in Chapter 7). Spaying may predispose such dogs to express these undesirable androgynous traits. O'Farrell and Peachey (1990) observed a similar effect in a subgroup of spayed female dogs. They compared the behavior of 150 spayed females with a matched (breed and age) control group of 150 nonspayed females. Spayed females showed a significant increase in dominance-related aggression following surgery, especially if they were under 1 year of age and had exhibited aggressive behavior prior to spaying. In addition, Podberscek and Serpell (1996) have reported that females spayed *before* exhibiting aggression were more likely to exhibit aggression toward children.

Progestin as a Testosterone Antagonist

Joby and colleagues (1984) performed a series of studies to investigate the effects of oral progestins on the behavior of intact male dogs. The sample included 163 dogs with a variety of behavior problems, ranging from dominance aggression to destructiveness. The dogs were administered a daily dose of megestrol acetate (1 mg/kg or 4 mg/kg—30 dogs required the higher dose) over the course of 2 or 3 weeks of treatment, depending on the dog's response to treatment. Most of the dogs exhibited more than one unwanted behavior problem. Of the 163 dogs presented for treatment, 123 (75%) showed improvement at the conclusion of a brief exposure to megestrol acetate. An interesting aspect of the study is the broad effect that progestin treatment had on remote behaviors not directly related to a sexual motivation, such as dominance-related aggression (79% improved), fear-related aggression (71%), destructiveness (79%), and excitability (73%). The primary side effects reported (in 36 dogs) by the authors was an increase in appetite and lethargy. After 3 months off medication, many of the dogs continued to exhibit lasting improvement, although some had relapsed somewhat. Recidivism was especially evident in the case of dominance aggression and household urine marking. The broad benefits of progestin are probably due to its general tranquilizing and anesthetic effects (Knol and Egberink-Alink, 1989a,b).

Note: Although the authors reported minimal side effects, the use of progestin therapy is now widely criticized because of the availability of alternative medications and the potential for serious side effects resulting from long-term use of such hormones.

Pseudopregnancy

Pseudopregnancy or *pseudocyesis* is a hormone-mediated condition that may reduce functional thresholds for aggressive behavior. Pseudopregnancy occurs in female dogs, usually 6 to 8 weeks after estrus, but in some cases not presenting for 4 or 5 months after estrus. In addition to mammary enlargement or lactation, various behavioral signs may present with the condition, including toy adopting, nesting behavior, hyperactivity, destructiveness, and aggression. Aggression thresholds may be generally lowered during the period of pseudopregnancy, with aggressive behavior being particularly likely to occur when the dog's nesting area or toy surrogates are approached. Destructiveness involving digging into sofas and carpeting may also occur during pseudopregnancy. Voith (1980b) has speculated that pseudopregnancy may have served an adaptive function for the dog's ancestors. She argues that the physical and behavioral changes associated with pseudopregnancy may be the result of evolutionary pressures favoring the communal care of young by closely related females belonging to the mother's group. Spaying is commonly recommended in the literature to control the problem (Houpt, 1991); however, spaying a dog while she is still exhibiting signs of pseudopregnancy may significantly protract the condition (Voith, 1980b), perhaps causing it to persist for years in some cases (Harvey et al., 1999). Consequently, spaying should be undertaken only after signs of pseudopregnancy have disappeared (approximately 4 to 6 weeks). Further, some females may develop signs of pseudopregnancy only after spaying, perhaps helping to explain some of the increased incidence of aggression in females after the surgery. In this regard, Borchelt (1983) found that spayed females were significantly more likely to engage in possessive aggression than intact counterparts. Further, in the only cases involving dominance aggression in intact females, it was later discovered that the females were under the influence of pseudopregnancy. Symptoms of pseudopregnancy are often controlled with sex hormones [e.g., progestins (Hart and Hart, 1985a)].

NUTRITION AND AGGRESSION

A great deal of speculation exists concerning the effects of nutrition on behavior, but little scientific knowledge is known about these effects. Animal behavior consultants commonly cite this or that nutritional imbalance as being responsible for causing or predisposing dogs to a exhibit a particular behavioral problem. Recommendations ranging from supplemental B complex for aggressive behavior to massive doses of calcium and other minerals for destructiveness have never been demonstrated clinically or in the laboratory. Campbell (1992), for example, claims that a positive correlation exists between relative protein/carbohydrate proportions in a dog's diet and general excitability levels. High protein levels supposedly decrease excitability while at the same time producing various benefits such as increased trainability. In the opposite direction, high carbohydrate levels are believed to increase excitability and promote distractibility. In addition, he recommends supplementing his stress diet with B complex as nutritional "insurance," even though the dog appears healthy without it. Unfortunately, no experimental data are presented to support these various recommendations or the hypotheses on which they are founded.

Over the past several years, a growing concern has been expressed regarding the effects of food coloring and chemical preservatives on the development of hyperactivity and other behavior problems (see *Dietary Factors and Hyperactivity* in Chapter 5). One result of this concern has been the production of a new generation of diets containing fewer additives—a change in dog food manufacturing that can do no harm, but the potential good of such diets is not clearly known or demonstrated. Research on this topic is scanty and, at present, little scientific evidence exists showing a direct causal relationship between food additives and the incidence of behavior problems in dogs.

However, some evidence does suggest that adjusting dietary protein levels may provide a viable means for influencing the behavioral thresholds of some forms of aggressive behavior (see *Diet and Serotonin Activity* in Volume

1, Chapter 3). For example, Mugford (1987) reported observing a significant decrease in aggressive behavior in a group of golden retrievers after they were placed on a low-protein diet. More recently, a multiclinic study that compared the effects of low-protein versus high-protein diets on aggressive behavior in dogs found that reducing dietary protein levels exerted a beneficial influence in dogs exhibiting territory-related aggression with fear (Dodman et al., 1996). The strongest evidence for a linkage between aggression and dietary protein levels has come from basic brain research. Numerous studies have indicated that dietary protein levels significantly affect the amount of tryptophan reaching the brain for the manufacture of serotonin (Spring, 1986; Christensen, 1996). Paradoxically, high levels of circulating protein in the blood may deprive the brain of adequate tryptophan. This effect is due to a transport mechanism responsible for the selective transfer of nutrients from the blood into the brain. When the blood contains high levels of protein, other relatively more abundant circulating amino acids compete with tryptophan for a limited number of transport molecules, thereby causing an impediment of tryptophan transport into the brain. This situation can be nutritionally modified by simultaneously lowering dietary protein levels while increasing the intake of carbohydrates. The ingestion of carbohydrate-laden foods stimulates the secretion of insulin. Insulin biochemically alters competing amino acids, causing them to move into surrounding muscle tissue. The net result is that tryptophan obtains a numerical advantage over other amino acids competing for limited transport channels providing passage through the blood-brain barrier.

Serotonin serves many important functions as a neurotransmitter, especially the management of stress, impulse control, and mood regulation. Decreased serotonin activity is associated with depression and increased irritability. Many antidepressant psychotropics are believed to work by increasing serotonergic activity. When serotonin levels are low, dogs may become more impulsive and irritable and exhibit a lowered threshold for aggressive behavior. Diets adjusted toward decreased protein intake (less than 18%) coupled with increased carbohydrate intake appear to exercise a mild threshold-raising influence, perhaps by enhancing serotonin-mediated impulse control and improving the brain's ability to manage stress. Recently, DeNapoli and colleagues (2000) have reported evidence suggesting that supplementation of the canine diet with tryptophan may exercise a significant modulatory effect over certain forms of aggressive behavior. In the case of dominance aggression, tryptophan supplementation of high-protein diets yielded a significant decrease in aggression scores. In the case of territorial aggression, scores were most strongly reduced in dogs that were fed a low-protein diet supplemented with tryptophan. Although this research is promising, increasing nutritional tryptophan levels may not necessarily result in an appreciable increase of serotonin production. Above a certain point, the rate-limiting factor, tryptophan hydroxylase, is saturated and unable to support further synthesis of 5-hydroxytryptophan (5-HTP)—the immediate precursor of serotonin (5-HT) (Christensen, 1996). Given the aforementioned limitation, supplementing the protocol diet with 5-HTP might have proved significantly more efficacious for enhancing serotonin production. In addition to being more directly and efficiently converted into serotonin than tryptophan, 5-HTP moves more freely through the blood-brain barrier (not needing to compete for transport molecules). Furthermore, unlike tryptophan, which remains banned from over-the-counter sale, 5-HTP is readily available and sold at health food stores (Murray, 1998)—a significant consideration if 5-HTP is ultimately shown to exert a beneficial effect on aggression problems in the dog.

Role of Integrated Compliance and Obedience Training

Most treatment programs for aggression problems incorporate some element of obedience training (Tortora, 1983; Blackshaw, 1991; Clark and Boyer, 1993; Reisner, 1997) or nonconfrontational compliance training (Line

and Voith, 1986; Campbell, 1992; Overall, 1997). According to Tortora (1983), the benefits of obedience training depend on treated dogs learning that safety can always be obtained by engaging in cooperative behavior. Similarly, Clark and Boyer (1993) have argued that obedience training promotes a "feeling of security" as the result of establishing clear lines of communication and social boundaries by selectively and consistently applying incentives and appropriate deterrents to guide and shape dog behavior. The efficacy of obedience training as a therapeutic tool has been confirmed by Blackshaw (1991), who reported a high success rate involving dominance and territorial aggression by introducing proper restraint techniques and obedience training as her primary form of behavioral intervention. Even those individuals who appear to discount the preventative value of obedience training as a *placebo,* exerting "neither positive nor negative effects on the incidence of behavior problems" (Cameron, 1997:271), may nonetheless recommend such training because "obedience training provides tools for owners to use in modifying pet behavior" (271). Finally, nonconfrontational compliance training utilizes the most simple obedience exercises (e.g., sit and sit-stay) and positive reinforcement to achieve secondary control over the expression of aggressive behavior (Voith, 1980a; Uchida et al., 1997).

Despite the apparent therapeutic efficacy of obedience and nonconfrontational compliance training, the role of such activities for the prevention of behavior problems remains controversial. Although the literature is conflicted and equivocal on the preventative value of training, many authors, nonetheless, suggest that training does appear to exert a strong preventative influence. For example, Overall (1997), an advocate of preventative compliance training, has claimed that dogs require *rules* and need a rule-based social structure to communicate and cooperate with one another and with humans, claiming that her type of compliance training (a highly intrusive variation on Voith's "nothing in life is free" program) provides a means for "preventing such problems and in treating all forms of behavioral problems" (410).

But the question remains: Does obedience or compliance training serve to prevent problems, especially aggression problems? With respect to obedience training, Voith and colleagues (1992) suggest that it may not perform a preventative function. In a study involving the analysis of 711 questionnaires filled out by dog owners visiting a veterinary hospital clinic, they found that obedience training (as well as spoiling activities and anthropomorphic attitudes) showed no significant correlation with a wide spectrum of behavior problems, including aggression. A subsequent study performed by Podberscek and Serpell (1996) also failed to show a linkage between obedience training and the incidence of aggression problems in English cocker spaniels (N = 596). Finally, in a case-controlled study involving 178 matched pairs of biting and nonbiting dogs, Gershman and colleagues (1994) failed to detect a significant statistical relationship between obedience training and the incidence of aggressive behavior.

More recently, upon analyzing the data extracted from a large sample (N = 2018), Goodloe and Borchelt (1998) reported that a preventative relationship *does* appear to exist between a history of obedience training and the occurrence of a variety behavior problems, including aggression. Obedience training was significantly correlated with a lower incidence of aggression in all categories analyzed, except aggression toward unfamiliar dogs. They also found that obedience training was generally correlated with better-behaved dogs in two complementary directions: a decrease of undesirable behavior and an increase of desirable behavior. These findings suggest that training may help guide and refine a dog's adaptation to domestic life, making it more successful and problem free. In addition to the obvious benefits of establishing limits and control, the authors suggest that the benefits of training may be related to various incidental aspects of interaction that are associated with the training process, including increased time spent with the dog, added exposure and socialization resulting from class attendance, and a better appreciation and understanding of dog behavior. This

study appears to contradict the earlier findings of Voith and colleagues (1992), which failed to identify a beneficial relationship between obedience training and the incidence of behavior problems. Goodloe and Borchelt note that the larger sample of respondents used by them may have provided a better statistical pool for detecting the beneficial influences of obedience training. They suggest that the earlier study performed by Voith and colleagues may have been too small to detect these correlations. Finally, Patronek (1996) has reported that dogs that participated in obedience classes were much less likely to be relinquished by their owners to an animal shelter.

Given the evident therapeutic value of obedience and compliance training, it is a bit astonishing that such training would not exert a more consistent and strong preventative influence over the development of aggression problems. This impasse is of considerable significance, since most treatment programs for aggression (especially dominance-related aggression) depend, in part, on some variant of obedience or compliance training. Behaviorally speaking, the treatment applied in advance (preventative training) should exert some mitigating influence over the problem, for the very same reasons that it presumably reverses it. Logically, in fact, one should expect the preventative effect to be far more robust and persuasive than the treatment effect, since the therapeutic influence must exert enough power to reverse already established aggressive behavior and prevent its reoccurrence (behavioral momentum). Further, most treatment programs are founded on the behavior-modifying effects of learning. Learning does not just occur when guided by an expert's recommendations or under the owners conscious efforts, but proceeds continuously insofar as a dog lives and interacts with its environment:

> One cannot choose to either employ or ignore the empirically established rules of learning. Much like the law of gravity, the laws of learning are always in effect. Thus, the question is not whether to use the laws of learning, but rather how to use them effectively. (Spreat and Spreat, 1982:593)

Given the apparently robust effect of behavior therapy, on the one hand, and the continuous influence of learning on the other, it is difficult to imagine how such things as obedience training, spoiling activities, and anthropomorphic attitudes would not have a significant effect on behavioral adaptation and the incidence of behavior problems.

PART 2: CHILDREN, DOGS, AND AGGRESSION

Preventing Problems

Children are often implicated in the development of serious dog behavior problems, especially those involving hyperactivity and aggressiveness. Many consultants recommend that a family not acquire a dog until the children are at least 6 or 7 years of age. This recommendation is based on a widely held assumption that children under this age lack sufficient maturity to treat a dog properly and safely. However, a child's age is not always a reliable marker of maturity. Older children may be more irresponsible and abusive toward a dog than their age would seem to indicate. In addition, younger children can be taught to interact with a canine companion safely and affectionately, often surpassing the ability of insensitive adults! Such matters depend on individual cases and on the parent's willingness to explain and demonstrate acceptable ways of behaving around a dog. In addition, the parent must provide adequate incentives and deterrents to ensure compliance by the child.

Sources of Conflict and Tension Between Children and Dogs

In the case of difficult children of any age, teasing and abusing the family dog is a prescription for disaster. Such behavior is often employed as a manipulative attention-seeking ploy and annoyance for the parent. Some older children see the dog as an easy and ever-available target for the release of pent-up frustration and redirected anger. Not surprisingly, abusive treatment of the dog often occurs after the child has been punished by parents

or by a teacher at school. In a rather bizarre and unsettling report exploring the psychosocial benefits of dog companionship for children, Bossard (1944) seriously recommends that dogs be used as ready objects for such hostile "personal needs" involving ego frustration and gratification:

> If things have gone wrong, and you feel like kicking some one, there is Waldo, waiting for you. If you have been ordered about by the boss all day, you can go home and order the dog about. If mother has made you do what you did not want to, you can now work on the dog. Long observation of children's behavior with domestic animals convinces me that this is a very important function. Often the child has been the victim of commands, "directives," shouts, orders, all day long. How soul-satisfying now to take the dog for a walk and order him about! This is a most therapeutic procedure. (411)

Recommendations like those of Bossard neglect to appreciate fully that a dog is a feeling victim, albeit silent and forbearing, until at last it is pushed to the limits of its tolerance and forced to defend itself with the familiar devastation for both the child and the dog.

Bossard also suggests that the family dog be used for sex education, arguing that "the external physical differences of sex can be seen, identified, and discussed, without hesitation or inhibition on the part of either parent or child" (411). Unfortunately, this sort of pedagogy may, in addition, facilitate abusive handling and treatment when a child is left alone to investigate and study the subject on their own. Inquisitive children may secretly offend their canine companions in forbidden ways—extracurricular activity that Bossard might have regarded as a vital and informative outlet for childhood sexual fantasies.

The incidence of such aberrant behavior among preadolescent children and the impact it has on dogs is not known. More information is available concerning the incidence of cynophilia/zoophilia among adolescent children. Kinsey and colleagues (1948, 1953) estimated that approximately 8% of the urban male population had experienced some sexual contact with an animal, whereas a surprising 40% to 50% of adolescent boys living in rural environments reported having sexual contact with domestic animals. Among adolescent urban women, 3.6% reported having sexual contact with animals, mainly (74%) involving dogs. Overall, the researchers conclude that sexual interaction between humans and dogs is relatively rare.

Children exhibiting abusive behavior toward the family dog should be referred to a child psychologist for evaluation (Ascione et al., 2000). Such activity may presage the development of more serious sadistic and violent behavior later in life. Many violent offenders abused animals as children. Also, animal-abusive children may themselves be the victims of similar abuse in the home. There are reports (Ascione et al., 2000) of findings of others indicating that pet abuse and neglect frequently present together. In one study mentioned, children exposed to sexual abuse were significantly more likely to abuse animals (27–35%) than nonabused counterparts (5%). Unfortunately, research is still lacking, but anecdotal reports and psychological case studies point to a significant relationship between child abuse and animal abuse.

Establishing Limits and Boundaries

To prevent problems, children must learn how to respectfully handle and care for their dogs. These efforts should include instruction involving appropriate and inappropriate play. Parents often assume that children instinctively know how to behave properly toward dogs. This wishful viewpoint is not always true, and some dogs are intolerant of play, just as some children are disinterested in the play of dogs. Further, children and dogs play in species-typical ways, containing movement messages that are only partially understood by each other and responded to as intended. Although significant evolutionary continuity informs the play habits of children and dogs, there are important differences in the way each initiates, interprets, and modulates their respective play activities (Rooney et al., 2000).

These fundamental behavioral differences are probably the source of many failures of children and dogs to get along together successfully. Under the guidance of a vigilant parent, both the child and the dog can learn how to play constructively with each other and avoid the risk of their playful efforts escalating

into problems. This is not always an easy process, but with perseverance and consistency the child (and the dog) can be taught to respect proper social boundaries and limits. Most importantly, the parent must be careful to set a good example for the child by avoiding inappropriate play and disciplinary efforts.

Another beneficial socializing influence on dogs and children is training. First and foremost, dogs should undergo sufficient training to establish the basic social boundaries: no jump, bite, chase, bolt, or pull. Once these boundaries are set, children can easily interact with their dogs on a friendly level and reinforce cooperative behavior with affection, food, and toys. Children should participate in the training process and practice with their dogs on a daily basis. Rewards of all kinds can be used by children to gain a surprising degree of control over their dogs. The primary benefit of such training is the provision of a foundation for effective interaction between the children and dogs based on enhanced communication, cooperation, compliance, and compromise. In addition, according to Levinson (1980), many subtle psychological benefits may be obtained by allowing children to participate in training activities:

> Part of acquiring autonomy is the taking over of control of one's behavior, the development of self-disciplining and impulse control. The ability to delay gratification, to exercise patience, to carry out responsibilities, to recognize and defer to the needs of others on occasion are all part of being a self directing human being. A child who is responsible for the well-being and training of a pet has to exhibit all these capacities. He is also trying to inculcate some of the abilities in his pet, who must wait to be fed or walked, will not always be played with on demand, must learn not to damage furnishings, etc. Of course, the more self-mastery the child has acquired the better he can train his pet, but the very act of trying to train his pet successfully will reinforce self-control to some extent. . . . Through trial and error in teaching his pet new tricks, the child discovers that he must at times control the frustration he feels when his pet is not learning as quickly as he would like. Through bitter experience he learns that scolding and punishment will only serve to delay or impede the pet's learning. As the child develops more tolerance for his pet's difficulties, he may become more tolerant of his own inability to master his lessons, less inclined to view himself as "stupid" or "bad." (69)

Even under the most favorable circumstances, children may be tempted to test limits with their canine companions. Such interaction might actually help children to build an empathetic appreciation of how their behavior impacts on others. Optimally, the dog offers itself as a living being with which the child can explore and *test* the effects of affectionate and caring treatment. However, even innocent behaviors like hugging and holding may be interpreted by a dog as threatening gestures, particularly while it is sleeping or eating (Voith, 1981). Teaching children not to disturb dogs engaged in these activities goes some way toward preventing unnecessary dog-bite incidents. Also, whenever possible, conscientious efforts should be made to decrease the amount of screaming and rushing around the dog. In the case of busy households, an open crate can be provided to the dog as a haven of security within the otherwise chaotic maelstrom of household activities.

In addition to training, children should be taught to avoid engaging dogs in improper and provocative play like roughhousing, chase-and-evade jousts, and inappropriate tug-of-war games. Exposing dogs to daily agitational play and excessive teasing may result in the development of adjustment problems, especially competitive excesses and hyperactivity. Children constantly teasing, screaming, and running wildly through the house are bound to unnerve even the most calm and docile dog. Such behavior on the child's part increases the dog's irritability while simultaneously lowering his threshold for aggression. Consulting trainers should draw attention to the dangers of such "play" and candidly suggest to owners ways of teaching their children better ways of behaving around dogs. Ideally, parent-owners should patiently guide children by explaining how such behavior adversely affects dogs. Children should be instructed to leave sleeping and eating dogs alone and not to tease them with toys or disturb them when they possess one. On the positive side, children should be taught alternative games like ball play and hide 'n seek. Finally, children should be explicitly taught how to touch and handle dogs properly in a calming and reassuring manner.

DOG AND BABY

A common reason for dog owners to seek professional advice is to learn how to introduce a baby *safely* into a household with a resident dog. Expectant parents seeking such information are often concerned about how the dog might react to the presence of an infant, but they are often especially apprehensive about the possibility that the dog might actually bite or otherwise injure the child. These fears may be based on unfounded worries or express legitimate concerns about the dog's behavior, based on previous overt displays of aggression toward family members, guests, or other animals. Even in those cases where no evidence of previous aggression exists, the expectant parent may still harbor reasonable fears about their dog's potential behavior toward the baby, based on more subtle behavioral signs and temperament traits.

Of course, the worst secret fear is that the dog might actually attack or kill the infant. Although this is a remote possibility, fatal dog attacks on babies are statistically rare and very unlikely if the owner takes the most basic precautions. Unfortunately, there exists an irrational and widespread exaggeration of the risks involved, making some owners unnecessarily fearful about the possibility of an aggressive incident. This perception may be a by-product of the way in which periodic serious or fatal dog attacks are handled by the news media. The occurrence of such horrifying incidents receive inordinate (and often irresponsible) national and international coverage. Such reports are shocking to the public. The dog is a cultural symbol of devotion, fidelity, and protection and, when a fatal attack occurs, it strikes a deep and discordant chord of curiosity and horror. It is not difficult to understand how such reports stimulate unnecessary foreboding about the family dog's reaction to the arrival of a new baby. Regrettably, the result of such misunderstanding is often the unnecessary relinquishment of a healthy and friendly dog to an animal shelter, thereby exposing it to a potentially tragic and unjustifiable fate.

Recognizing that such apprehensions probably exist (unconsciously or consciously) in the minds of many parents, dog behavior counselors should allay or dispel such fears by explaining that dogs rarely attack or kill babies. Nonetheless, commonsense precautions should be taken to make the transition an easy and uneventful one for both the dog and the infant. Although most dogs represent a minimal risk to infant children and ultimately make suitable companions, some dogs are simply too dangerous to be in close contact with young children and should be placed into a home without children. Many owners express fears that the dog will resent the baby, perhaps *acting out* toward the infant as the result of sibling rivalry or jealousy. These owners need to be reassured that the dog is not likely to behave aggressively toward the infant as the result of jealously, but excessive *rivalry* for the owner's attention may increase the risk of problems arising as the result of competition for the owner's attention and contact. Although the vast majority of dogs are not likely to attack or otherwise hurt a baby, a dog does represent some degree of risk to a helpless infant and, therefore, should be evaluated and receive sufficient training *before* the baby comes into the home, rather than waiting until problems arise. These situations are often very complicated and should receive the utmost care and professional attention.

EVALUATING THE RISK

The average dog owner is often unable to assess objectively their dog's potential threat to the infant. Consequently, an important service rendered by dog behavior consultants is to provide an assessment of the various risks involved and to advise owners on how to minimize them. This can be a very uncomfortable and onerous responsibility, since a number of serious decisions have to be made that may dramatically affect a dog's future, based largely on a consultant's findings and recommendations. Furthermore, although many risk factors have been identified (Voith, 1984; Wright, 1985; Riegger and Guntzelman, 1990; Mathews and Lattal, 1994), no evaluation procedure currently exists that provides a *certain* determination of risk. Ultimately, such assessments rely on available scientific information, a history of aggressive behavior, and, most importantly, *gut* feelings about the dog and the situation.

The telephone interview provides valuable information about the dog and the family situation. An important goal of the initial interview is to develop a preliminary risk assessment of the immediate danger of bringing an infant into the home. The information obtained should include (at least) the following: the dog's sex and status, age, breed or mix, general activity level, training history, past socialization with children, evidence of predatory behavior toward small animals, history (e.g., place, frequency, and persons involved) of aggressive behavior toward people, type of aggression involved (e.g., dominance related, fear related, predatory), and history (e.g., place, frequency, and dogs involved) of aggressive behavior toward other dogs. Initial findings like these provide a risk profile based on salient behavioral, physical, and temperament factors.

The following profiles exemplify the opposing directions of high risk and low risk:

High-risk profile: A 2-year-old male (intact) dog with minimal previous contact with children. When exposed to children, the dog exhibits signs of increased irritability and nervousness. The dog has not received significant training, bolts out of control if given a chance, guards (growls and snaps) over food and toys, threatens guests (must be leashed for their protection), and has a history of chasing and killing small animals.

Low-risk profile: A 1½-year-old female (spayed) with a gentle disposition toward children with whom she has had steady contact. The dog attended puppy classes and has received 10 weeks of obedience training, she is playful and affectionate toward people and other dogs, enjoys ball play and brings the ball back, exhibits an enthusiastic greeting toward everyone (animals and humans alike), and never guards food or toys.

Obviously, most family dogs fall somewhere between these two extreme profiles, with a few exceptional dogs situated above and below them. Although the hypothetical dog profiled in the high-risk category has never actually bitten anyone, he still represents a serious potential threat to a baby. Generally, rather than tolerate the dangers posed by a dog with a high-risk profile, the owner is advised to rehome the dog and to consult further with their veterinarian about other courses of action to consider. Clearly, anticipating such problems and rehoming the high-risk dog into a home without children would be preferable to waiting until a definitive incident occurs, perhaps leaving only one recourse available—euthanasia.

In such cases, astute counselors make it a practice to error on the side of safety and caution, rather than to make a grave mistake that could result in serious injuries and catastrophic consequences for the victim and the trainer alike, potentially including very serious legal and professional repercussions. Unfortunately, the behavioral risk presented by high-risk dogs to children may not be significantly alleviated by the most conscientious and intensive training efforts. Again, rather than waiting until it is too late, it is far better for all involved to rehome high-risk dogs and to discourage their owners from pursuing behavior modification and training. In addition to the risk factors listed in Table 6.3, some dogs may become progressively irritable and intolerant of contact as they grow older, either as the result of physical disease and discomfort or due to geriatric cognitive deficits. Interestingly, female dogs are twice as likely as males to exhibit geriatric or *late onset* aggressiveness (Hart and Hart, 1997). Also, according to this research, male dogs are more likely to become less aggressive as they age than are female counterparts.

In addition to evaluating the dog, it is important to consider the family situation, as well. This is particularly important in *borderline* cases where a successful transition will depend on the family's ability to faithfully carry out the various instructions provided to them. One especially problematic situation involves families that are divided about the dog's continued residency in the home. In such cases, one owner may be very fond of the dog and willing to assume the full responsibility for its training, but the other spouse may be overtly hostile toward the idea or secretly harbor serious misgivings and actually prefer that the dog be rehomed or euthanized. The reluctant partner might even go along with the idea of training the dog, often to

TABLE 6.3. Significant risk factors for aggression toward children

Lack of significant obedience training, especially in highly active, controlling, or independent dogs that resist efforts to control them.
Little or no significant socialization with children, especially if combined with evidence of fear or past aggression toward children.
Possession-related aggression over food, toys, and places.
Overly sensitive to touch or exhibit obvious signs of fear when approached with outstretched hands.
Fearful and slow to adapt to new situations, especially if the dog becomes avoidant or aggressive toward nonthreatening contact with children.
A history of preying on small animals, especially if it includes killing after the chase.
History of dominance-related aggression, especially in cases where the dog exhibits aggression when awakened from sleep.
Dogs that react to minimal frustration with aggression.
Dogs kept outdoors or chained most of the time.

placate the determined spouse defending the dog. When all is said and done, though, he or she may refuse to recognize the dog's progress, ultimately demanding that the dog leave despite good progress. This is a no-win situation that can be detected and avoided by a skillful counselor during the initial interview with the family.

The natural and easy way that dogs and children appear to get along may produce a perilous misunderstanding and complacency about the risks involved when introducing a newborn infant to the resident dog. As a result of this unwise perception, the infant may be put at great risk by being brought home and presented to the dog without much advance preparation to make the transition more safe and uneventful. On the other extreme, some dog owners are irrationally fearful of what the dog might do to the newborn child, even though it has never exhibited any real evidence of being a significant risk. Instead of working with the dog, they simply remove the "threat" from the home.

PREVENTING BITES

The child and dog have enjoyed an age-old comradeship. While reading W. Fowler Bucke's (1903) study of children's attitudes toward dogs, one is struck by the perennial and universal way children perceive and appreciate dogs. Unfortunately, children do not always interpret correctly the risks involved. Many situations involving bites are obviously evoked by children by placing dogs under some form of physical or mental duress. One of Bucke's young correspondents wrote,

> During the summer he had sore ears. One day I was playing near the door. Mother had just said, "Be careful, do not pull Bowler's sore ears." I did not heed mother's word, but went on climbing up his back by holding on to his ears. The poor dog endured the pain as long as he could, and suddenly snapped at me, biting my lower lip. When the doctor came I was lying on the sofa near the window. The dog came and looked in the window, and gave a pitiful whine, and for several days went about with his head down, and his tail between his legs. I begged father not to kill him, as he threatened to do. (493)

Many attacks delivered by family dogs upon children are produced by similar causes; that is, the dog bites only under provocative and easily avoidable circumstances. The bites involved are typically well directed and inhibited, occurring once, and have a self-protective character and purpose. Dogs that undergo daily abuse at the hands of their *own* child companions may be incredibly forbearing and may never attempt to bite *them,* but, woe, let another child enter the house unexpectedly or approach the dog in a startling way, and a very serious attack may occur.

How can dog bites be prevented? An adequate answer to this question involves addressing at least three equally important areas:

1. Educate the child about the dangers of mistreatment and teach him or her how to interact appropriately with the family dog and other dogs.
2. Provide the dog with adequate training and socialization around children and strangers.
3. Reward breeding efforts that emphasize temperament and intelligence over good looks.

One of the most frequently cited causes for the apparent increase in aggressive behavior in recent years is the dog world's favorite whipping boy and black sheep—the *puppy mill.* Although a convenient and worthy target of blame for some of the modern dog's plight, the puppy-mill hypothesis can hardly account for all of the dog's problems. Dogs acquired from pet stores represent only a small fraction of the total dog population, with approximately 7% of all dogs registered by the American Kennel Club being obtained through that venue (Shook, 1992).

As destructive as the puppy-mill situation is, it can hardly shoulder all of the blame for the alleged degeneracy afflicting purebred dogs (Lemonick, 1994). Other equally unscrupulous breeding practices for show and profit have also played their part. Although dogs acquired from pet stores often have behavior problems, their contribution to the aggression problem is eclipsed by dogs derived from other sources, including those bought from professional and hobbyist breeders. Reisner and colleagues (1994) at Cornell University, for example, found that dogs purchased from pet stores represent only 9% of the total number of dogs with serious dominance-related aggression problems. On the other hand, dogs bred by breeders constituted 68% (professional, 24%; and hobbyists, 44%) of the 109 cases of dominance aggression presented for treatment.

Aggressive behavior is influenced by an amalgam of acquired and biological factors. Consequently, if the problem of dog aggression is to be addressed, it will take a cooperative effort consisting of responsible breeding, competent training, and education. Responsible breeders can begin by placing an equal or greater emphasis on temperament and function, rather than focusing too much attention on form and good looks. Also, breeding should encourage traits conducive to harmonious family life, rather than perpetuating traditional and obsolete functions that have lost their usefulness. Finally, in addition to sound breeding practices, a dog's innate potential can be fully actualized only by the beneficial influence of early and lifelong training, aimed at perfecting the dog's social and domestic adaptation to modern circumstances and demands.

7

Intraspecific and Territorial Aggression

Lo, when two dogs are fighting in the streets,
With a third dog one of the two dogs meets;
With angry teeth he bites him to the bone,
And this dog smarts for what that dog has done.

HENRY FIELDING, *TOM THUMB THE GREAT* (1918)

PART 1: INTRASPECIFIC AGGRESSION

Competitive interaction between dogs results from a variety of complex social and territorial interests. Many of the same issues affecting aggression toward humans (interspecific) also affect aggression exhibited between dogs (intraspecific). But, unlike interspecific threats and attacks, intraspecific aggression also appears to be motivated to some extent by sexual-reproductive imperatives. Dog fighting

occurs under two broad circumstances: (1) between dogs not sharing the same household (nonresident directed) and (2) between dogs sharing the same home (resident directed). Most interdog aggression takes place between dogs of the same sex.

ETIOLOGY AND ASSESSMENT

Fighting is common among dogs and often results in serious and expensive injuries to combatants and to people, who are frequently bitten while attempting to separate gnashing and thrashing antagonists. The behavior is particularly prevalent among male dogs, but female dogs may also become determined fighters, especially females that live together in the same household. Urban dogs appear to be relatively more likely to develop a fighting problem, with most dog fights occurring between dogs walked off-leash in the late afternoon or night (Roll and Unshelm, 1997). The higher incidence of fighting among this particular population of dogs may occur because of the close daily contact they have while being walked on narrow sidewalks or exercised together in city parks. For obvious reasons, the powerful working breeds, especially shepherding dogs, are most commonly involved in fights that result in injuries requiring veterinary attention, but severe fighting is certainly not limited to such breeds. Intraspecific intolerance is recognized as a typical feature of terrier-type breeds (Scott and Fuller, 1965). Sherman and colleagues (1996) found that terriers presented disproportionately with fighting problems but only with respect to nonresident targets. Also, male and female dogs appear to differentiate in terms of the context and targets of intraspecific aggression. The majority of nonresident-directed aggressive episodes involve unfamiliar intact-male dogs obtained from breeders (Roll and Unshelm, 1997), whereas most resident-directed aggression involves spayed-female combatants (Sherman et al., 1996).

Many factors influence the development of intraspecific aggression. Determining the targets and the exact situations where fighting breaks out is useful information. Does a dog exhibit aggression toward all dogs regardless of their sex or status (castrated/spayed)? Does a dog exclusively fight with members of the same sex? In the case of dogs that live together, does fighting ever occur in the owner's absence? Is fighting more likely to break out in the presence of any particular family member? Answers to questions like these and others are extremely useful for properly evaluating the problem and helping to select the most appropriate course of training and behavior modification. Dogs fight with one another for many different reasons. Although dogs may be biologically inclined to exhibit such behavior, the effects of early socialization, traumatic events involving other dogs, and a dog's history of fighting should be carefully assessed. This is especially significant when evaluating aggression that is highly generalized and targeted against both male and female dogs, regardless of context.

OWNER CHARACTERISTICS OF *AGGRESSORS* AND *VICTIMS*

Roll and Unshelm (1997), who collected and analyzed questionnaire information from dog owners (N = 206) seeking emergency treatment after a dog fight, found clear differences among the owners of aggressors (N = 55) versus the owners of victims (N = 151). Unfortunately, the authors neglected to interpret their findings (see Table 7.1), and it is difficult to see how they might influence the development of interdog aggression. In practice, many owners of aggressors are in active denial with respect to their dog's behavior, often refusing to come to grips with what the dog is doing. They are prone to engage in diverse and capricious interpretations of their dog's aggressiveness in order to avoid the painful recognition that their beloved dog is a public threat and menace. Frequently, their explanations take the form of irrational justifications and rationalizations designed to mitigate the seriousness of the dog's behavior, to make excuses for it, or to lessen the dog's culpability and, perhaps, their own responsibility for it (Sanders, 1999). Other owners may be indifferent or exhibit an unusual degree of tolerance for such behavior. Some may condone the behavior or hesitate to correct it, fearing that such efforts might inadvertently suppress more desirable protective tendencies. These

TABLE 7.1. Owner characteristics of aggressors and victims

Owners of aggressors
Mostly males who were self-employed or academics aged between 30 and 39 years.
They tend not to form emotional relationships with their dogs and often report having owned dogs for most of their lives.
They consciously select specific breeds and show interest in protection training (Schutzhund).
They tend to obtain dogs for security reasons.
Dogs are often trained through physical force.
During the fight itself, owners of the aggressor may react impassively and shout at the dog only after the fight has come to an end. Many of these owners (40%) show no reaction at all, during or after the fight.
Owners of victims
Many owners of victims are women who are housewives or pensioners.
They often keep dogs for the prevention of loneliness and safety.
They do not tend to select their dogs on the basis of breed considerations.
Dogs are trained by less forceful means.
Fewer owners of victims report having owned dogs most of their lives than reported by owners of aggressors.
Owners of victims will often attempt to console their injured dog after a fight.

After Roll and Unshelm (1997).

concerns are not necessarily allayed by explaining that protective aggression and dog fighting are not necessarily linked with each other; in fact, dog-aggressive dogs are usually surprisingly friendly and outgoing toward people. Finally, a special case exists in which the owner secretly takes pride in the dog's dangerous behavior. Such owners appear to project their own aggressive fantasies and insecurities vicariously upon their dog, thereby exploiting and victimizing all involved for the sake of their own perverse and cowardly pleasures.

DOMESTICATION AND DEVELOPMENTAL FACTORS

Phylogenic Influences

The tendency to fight is a phylogenetic or species-typical trait. The tendency predisposes many dogs to engage other dogs of the same sex in agonistic contests, primarily involving ritualized displays and assertions of dominance. In general, however, the trend among the majority of domestic dogs is in the direction of exhibiting maximum tolerance and minimum aggression when interacting with conspecifics. Over many centuries of domestication and selective breeding, the dog's physical structure, physiology, and behavior have undergone dramatic transformations, resulting in a significant biological divergence from the ancestral prototype on many levels (Frank and Frank, 1982). The dog's appearance and behavior have been strongly influenced by a pervasive process of neoteny, causing it to remain more puppylike as an adult than the wolf. Neoteny has also disrupted the normal developmental expression of various instinctive behavioral and communication systems. Relevant to the present discussion is the finding that these neotenous changes in the dog's appearance may impede its ability to express and receive unambiguous threat and appeasement displays (Goodwin et al., 1997). Besides making dogs appear more puppylike, neotenic changes appear to have elevated fear and aggression thresholds in dogs while simultaneously lowering the threshold for affiliative behavior and play. In most well-socialized dogs, close friendly bonds and playful interaction overshadow and restrain the expression of fear and aggression (Bradshaw and Lea, 1992).

Despite these general trends among the majority of dog breeds, some guard and fighting breeds may have undergone specific genetic changes that cause them to respond abnormally to conspecific agonistic threat and appeasement displays (Lockwood and Rindy,

1987). In such dogs, genetically lowered thresholds for overt damaging attacks appear to take priority over ritualized aggressive contests. Also, guard-type and fighting breeds may have undergone genetic alterations enabling them to tolerate pain at more intense levels of stimulation than the average dog—all factors contributing to their aggressive tenacity and *gameness.* Besides hardness of bite, such breeds often exhibit a notorious unwillingness to let go once the bite is secured, sometimes requiring extreme measures to get them to release their hold (Clifford et al., 1983).

Ontogenic Influences

Playful competition can be observed in young puppies shortly after they enter into the socialization period around week 3 (see *Learning to Relate and Communicate* in Volume 1, Chapter 2). These agonistic activities escalate over the ensuing weeks until much of the interaction between puppies is devoted to aggressive play and sparring. Some litters are more aggressive than others, but all healthy puppies play aggressively with one another. A possible purpose underlying early aggressive contests is the establishment of a hierarchically stratified group, resembling in many important respects an adult pack. While establishing relative dominance among littermates appears to be an important function of aggressive play, it also appears to be done for its own sake, that is, for the sheer physical exertion and pleasure of it. As puppies develop, the intensity of their fighting may escalate and involve more than two playful combatants, with puppies aligning themselves cooperatively in order to outnumber and subdue an opponent. Occasionally, the lowest-ranking puppy is at risk of receiving excessive mobbing by the rest of the group and may need to be removed to avoid injury or emotional trauma (Scott and Fuller, 1965).

HORMONAL INFLUENCES

Hormonal activity appears to influence the expression of intraspecific aggression (see *Hormones and Aggressive Behavior* in Chapter 6). Intact males are the most common aggressors and targets of attack (Roll and Unshelm, 1997). An androgen surge in the male dog during the adolescent period between months 6 and 8 (Hart, 1985) may exert a pronounced influence on behavioral thresholds regulating aggressive behavior between dogs. These hormonal changes are frequently associated with the simultaneous appearance of heightened intermale aggressiveness and urine-marking activities. Adult males appear to be particularly intolerant and hostile toward other intact males coming into puberty. Such aggressive challenges and frisks do not usually escalate to the scale of damaging fights, but this rule is definitely not always the case, since not all adolescents subordinate themselves without offering a contest. This increased aggressive interest and targeting of intact adolescents may be under the influence of olfactory pheromonal cues and the often taunting and *uppity* behavior shown by adolescent dogs. Not only are adolescent intact males more attractive as targets, they themselves are much more provocative than castrated counterparts or females. Castrated dogs, in contrast, belonging to this age group are far less likely to attract the aggressive interests of mature intact dogs. In general, castrated dogs appear to be less aggressive toward other male dogs and more apt to submit, rather than fight back, when challenged. Male dogs rarely direct their aggression toward females, except in cases in which the female attacks first. And, even then, the resulting skirmish is often more a picture of confused self-defense than fierce fighting.

Castration and Dog Fighting

Since there appears to be a clear correlation between the development of intermale aggression and adolescent hormonal activity, a preventative measure that ought to be considered is early castration. Hopkins and colleagues (1976) found that 63% of dogs showing intermale aggression exhibited either a rapid decline (38%) or a gradual decline (25%) of fighting activity after castration. More recently, Neilson and coworkers (1997) reported,

> With regard to aggression toward other canine or human members of the family, approximately 25% of dogs can be expected to have a

> 50 to 90% level of improvement after castration. A comparable reduction in aggression toward unfamiliar dogs or human territorial intruders can be expected in 10 to 15% of dogs after castration. (182)

For optimal preventative effects, the surgery should be carried out sometime between months 5 and 6, although the benefits of castration on such behavior do not depend on a dog's age at the time castration or the duration of the problem. Some evidence suggests that castration performed between weeks 8 and 12 may produce even more pronounced effects (Lieberman, 1987), but the actual benefits of early castration remain controversial. However, this option may be seriously considered in the case of individuals belonging to breeds prone to dog fighting. It must be emphasized, however, that even early castration will not necessarily prevent the development of dog fighting. Many individuals that have undergone preadolescent castration still exhibit strong intermale aggressive tendencies. This effect may be due to perinatal androgenization occurring just before and after birth.

Urine Marking and Intermale Aggression

Although a causal relation between urine-marking behavior and territorial aggression has not been definitively established in dogs (see below), some authorities strongly believe that such a causal relation probably exists. The assumption that urine marking is a causal precursor of territorial aggression has resulted in treatment programs in which dog owners are instructed to discourage their dogs from urine marking away from the home, especially in cases involving interdog aggression (Campbell, 1974; Juarbe-Diaz, 1997). Apparently, following Campbell's logic (although not citing him as her source of information), Juarbe-Diaz (1997) suggests that a major motivation of nonhousehold intermale aggression is the defense of urine-marked territories. Along with Campbell, she recommends constraining such aggressors from eliminating away from the home *territory,* "because this is believed to extend their territory beyond the boundaries of their owner's property" (504). This treatment program is of questionable value, not only because there is no credible evidence showing that it actually works, but, more importantly, because such restriction is highly intrusive and very difficult to implement. Further, simply because urine marking and intermale aggression appear to occur together in the same dog is not proof that the one habit is causally related to the other or that restricting the one activity will significantly limit the expression of the other. If such a causal link exists, dogs isolated to yards and rarely walked should be much less aggressive toward conspecifics than dogs walked and allowed to urinate freely; this has not been proven to my knowledge. Lastly, Hopkins and coworkers (1976) found no effect of castration on territorial aggression, even though castration exerted a pronounced effect on marking behavior. Other relevant studies have shown only a very slight benefit from castration on aggression related to territorial defense [see Neilson et al. (1997)]. Although increased urine marking and intermale aggression may share a common source of causality at some level of functional organization [see *Arginine-Vasopressin (AVP) and Aggression* in Volume 1, Chapter 3], the frustrative inhibition of one habit will not likely help to suppress the other; on the contrary, such efforts might actually potentiate it, thereby making matters worse. A major source of concern with the recommendation is that the abrupt restriction of urine-marking activity may instigate iatrogenic elimination problems, such as marking inside the house. Finally, urine marking is a normal canine activity that appears to represent a significant source of pleasure and excitement for dogs and, unless significant evidence is made available to support the notion that its restriction can significantly aid in the control of interdog aggression, it would seem advisable to let dogs urinate where they sniff fit to do so—as long as it is done outside of the house.

Socialization and Aggression

An important factor in the development of intraspecific aggression is the quality and quantity of early socialization. Puppies taken too early from the litter (before week 6) may become socially intolerant toward other dogs as adults. Even in cases in which puppies are

removed from the litter at an optimal time for secondary socialization with people (e.g., around week 7 or 8), the social learning needed to interact confidently with other dogs is not complete. Subsequent to adoption, the average puppy is only infrequently exposed to other dogs, perhaps further compromising the social skills needed for peaceful interaction. Roll and Unshelm (1997) report that nearly half of the aggressors and victims in their study were described as having few interactions with conspecifics between the ages of 5 weeks to 5 months. Such socialization deficits can be ameliorated by exposing a young puppy to other dogs of its age group through various activities like puppy kindergarten or play groups.

Even when a puppy remains with the litter throughout the socialization period, the experience itself may predispose it in various ways to react aggressively toward other dogs as an adult, especially unfamiliar dogs perceived as not belonging to its social group. This is particularly true in the case of puppies situated on either extreme of the dominance hierarchy. An *omega* subordinate, having undergone excessive or traumatic badgering by higher-ranking littermates, may consequently become progressively agitated and defensive toward other dogs. Such puppies can be surprisingly difficult to handle and train because of their sharpened reactivity to close social contact. As a result of their early experiences, they may become conditioned to react defensively when approached or touched. On the other hand, an *alpha* puppy may be influenced adversely by an opposite set of early social experiences, especially the successes it experienced while threatening and subordinating littermates. As an adult, the *alpha* puppy may be more prone to exhibit intolerance toward male conspecifics and actions perceived as *status* threats. Socially controlling or *dominant* puppies have been socialized to be aggressive and unyielding—early learning that often must be countered with remedial training. The most socially adaptable puppies are those that fall somewhere in the middle of the dominance hierarchy. Such puppies know how to assert themselves effectively and to occupy dominant roles or, conversely, they can submit and play subordinate roles when it is in their best interest to do so.

Early Trauma and Fighting

Many fighting problems stem from unpredicted attacks perpetrated by strange dogs. Although most adult dogs are gentle toward young puppies, some are not so inclined and may trounce defenseless youngsters, sometimes causing a lasting fearful psychological impression, making the victims wary of such contacts in the future. Such experiences appear to underlie the later development of some forms of intraspecific aggression. Puppies exposed to such attacks are susceptible to develop a prejudice against other dogs belonging to the aggressor's breed type or generalize more broadly in terms of the aggressor's size and color or simply learn to react defensively to all unfamiliar dogs. Many owners report a single surprise attack as the sole precipitating cause of their dog's fighting problem. Affected dogs appear to strike preemptively in an effort to assume the defensive advantage of a forceful offense. Such dogs, affected by the belief that they cannot predict when an attack might occur, may become increasingly vigilant and treat every encounter as though it represented a serious threat.

Territorial Agitation

Some dogs have developed intense aggressive attitudes toward other dogs as the result of territorial intrusion or violation. This is especially the case in dogs restrained on a chain and stake or kept behind fencing exposed to passing dogs. Dog fighting along fence lines is a common problem. Both males and females engage in this behavior, but it is a particular favorite of intact males, especially when the target is another male dog. The fence line is very problematic when it is shared with a neighboring dog, since it simultaneously demarcates the *intruder's* territorial boundary as well as the defender's. In nature, such situations rarely, if ever, develop. Territory is safely ensconced deep within a home range that is regularly inspected for intrusion. Under natural conditions, distant scent marking and various remote activities such as vocalizations and obvious evidence of pack residency like past kills and fecal deposits serve to ward off all but the most persistent intruders. Such terri-

torial devices serve to prevent inadvertent territorial overlapping between neighboring animals and, thereby, prevent unnecessary intergroup agitation, competition, and the potential for dangerous fighting.

Under domestic conditions, these territorial mechanisms are frequently ignored or violated, leading to heightened reactivity and the constant threat of serious attacks. In the case of fence fighting, intense aggression is frequently seen because both dogs claim the same boundary as their own. Since nothing is ever resolved one way or the other and both remain protected from each other, fighting escalates and becomes ritualized, frustrative, and very persistent. Many fence fighters develop various compulsive weaving, whirling, and fence-running habits. Although dogs have broken teeth on chain-link fencing and experienced other superficial injuries as the result of such fighting, the real problem involves kindling effects and the fostering of more general aggressive reactivity and aggressive biasing toward other dogs.

The agitation of daily fence fighting and the heightened aggressive arousal associated with it stress dogs, as well as facilitate the development of various undesirable behaviors: hypervigilance, hyperactivity, frustrative oral and somatic activities (chewing and digging at fence lines), and excessive barking. In addition, such unrestrained behavior is at risk of being redirected toward nearby people or dogs. When more than one dog is defending a fence line against intrusion, the situation can easily escalate into an outbreak of fighting between erstwhile defenders. Furthermore, unchecked aggressiveness near fence lines may inadvertently encourage dogs to become aggressive toward children and others walking nearby. The influence of fence fighting on territorial defense is discussed in greater detail in Part 2 of this chapter (see *Sources of Territorial Agitation: Fences and Chains*).

Virago Syndrome

While fighting behavior problems are most typically associated with male dogs, female dogs may also engage other dogs (male and female) in aggressive contests. This is especially the case with females living together in the same home. Females tend to establish a separate dominance hierarchy from that of males. Interfemale aggression is often intense and frequently involves injury. Causal factors appear to involve reproductive rights and privileges of dominance. Among wolves, only the alpha female is permitted to procreate. The alpha female appears to protect this privilege by hounding and harassing other mature females. This bickering and agitation appears to psychologically stress potential rivals, thus preventing them from entering a receptive and fertile estrus (see *Stress Hormones and Aggression* in Chapter 6). At such times as these, intense conflicts may flare up and grow into overt and damaging dominance fights. This pattern of birth control does not always work, however. In those cases where a subordinate interloper mates successfully, the punishment may be severe—her death. Wolves rarely fight to the death, but this is one situation where such fighting has been observed at least among captive wolves (e.g., Wolf Park, Battle Ground, Indiana). Breeders should be careful when breeding a subordinate female that lives in a situation with a more dominant female.

Aggression Between Opposite Sexes

Although resident-directed aggression between opposite-sex combatants is less common, when it does occur females are twice as likely to initiate attacks against male dogs than male dogs are to initiate attacks against females (Sherman et al., 1996). The mildest form of such fighting occurs when an unreceptive female rebuffs the advances of an unwanted suitor. The male usually accepts the rejection without retaliation, although he may persist in his seductive adventures until more fully convinced of her sincerity. Occasionally, however, a male may answer in kind, sparking a more serious battle of wills that may escalate into serious fighting. Another source of intersexual agonistic behavior can be observed when two puppies of the opposite sex are raised together. Although larger and, perhaps, more aggressive in general terms, the male is often pitifully subordinated by the relentless harrying of the more dominant female. The inclination for females to attack or excessively

dominate conspecific males is here referred to as the *virago syndrome.* As an adult, a viraginous female may engage the opposite sex in earnest fighting but not to the exclusion of members of her own sex, which she will also readily fight. This is a somewhat disconcerting situation for a male that does not recognize the female as a target for aggression and may be nonplused by her intentions. As a result, many males halfheartedly defend themselves, give ground, fumble over themselves, and simply retreat if they can. Such safe and successful consequences may be very reinforcing for a victorious female, encouraging her to instigate other aggressive challenges when encountering male dogs. Although many males do give ground, even very dominant males that would readily fight if it were another male making such trouble, she will eventually encounter a male that will not back down, with great potential for a serious and damaging fight.

Few unlimited generalities can be made about virago females other than their tendency to fight male dogs. Many are somewhat larger than others of their breed, and they often have a masculine appearance, exhibit some malelike behavior patterns, and are frequently aggressive in other ways besides dog fighting, including aggressive behavior exhibited toward people. Virago females urinate more frequently than is usually the female's custom, sometimes raising their leg in an effort to squirt onto vertical surfaces.

Perinatal Androgenization

One potential etiological basis for the development of the virago syndrome and other forms of heightened intraspecific aggression in females may stem from prenatal influences brought about by vagrant testosterone in amniotic fluids. Strong experimental evidence suggests that female embryos situated between males in the uterus are more likely to develop malelike aggressive tendencies and scent-marking patterns than are counterparts otherwise situated. Although this effect has not been directly demonstrated in dogs, it has been observed experimentally in mice and guinea pigs (Knol and Egberink-Alink, 1989). Some suggestive evidence regarding the effects of perinatal androgenization of female dogs has been reported by Coppola [1986—see Borchelt and Voith (1996)]. Among 14 female dogs presenting with dominance aggression and an increase of malelike behavior after spaying, he found that female aggressors were more likely to have been from litters predominantly composed of male puppies. Supportive evidence for this hypothesis has been reported by Beach and colleagues (1982), who exposed female dogs to testosterone prenatally and postnatally in an effort to determine the long-term effects of early androgenization on adult agonistic behavior. The researchers subsequently tested the androgenized or *pseudohermaphroditic* females for relative dominance ranking in dyadic pairings with adult intact males and spayed females. The paired dogs competed against one another for access and control of a bone. When male dogs were paired with spayed females, the former controlled the bone in 78 of 100 encounters. The androgenized females were similarly effective against spayed females, controlling the bone in 70 of 100 encounters but were only 39% of the time successful against intact males. When the androgenized females were already in possession of the bone and then challenged, they did not fare much better than spayed females against the males' effort to expropriate the prize. One significant difference did emerge, however: the androgenized females were much more aggressive, threatening males in 78% of the encounters compared to 20% of the time by spayed females:

> Males were threatened by P [pseudohermaphroditic] possessors in 78% of the tests compared with 20% for the F [spayed females] possessors. In 12 of 61 tests, a P possessor and a M challenger fought vigorously, but in all instances the M emerged as victor. . .. The aggressive behavior of P possessors was maladaptive in that it did not constitute successful defense. Although they always lost the bone, several Ps engaged in fights repeatedly. This was the outcome of strong reluctance to yield possession and a heightened tendency toward contentious behavior. (873)

Clearly, perinatal exposure to testosterone enhanced the pseudohermaphroditic females' dominance ranking over spayed females but not toward intact males. The observation by

Beach and colleagues that androgenized females are more aggressive and ready to fight maladaptively is of some significance to the role of testosterone in the expression of competitive aggression. Incidentally, androgenized females eliminate in the familiar raised-leg fashion of male dogs.

Aggression Between Dogs Sharing the Same Household

The majority of aggressive episodes involving dogs sharing the same residence are initiated by the youngest and most recently obtained member of the group. Statistically, as already mentioned, females are more likely than males to fight with one another when living in the same household. Also, aggression between resident dogs frequently results in more serious injuries to the combatants than observed in the case of nonresident fighting (Sherman et al., 1996).

In domestic situations involving two or more dogs, ritualized fighting is a common occurrence. This is especially the case where the dogs are of the same sex. Three basic forms of aggressive interaction can be observed among dogs sharing the same residence: (1) aggressive play that involves many of the behavioral components involved in actual fighting but without the intention to subdue or injure the opponent; (2) actual dominance fighting clearly designed to subordinate the opponent but without injuring it; and, lastly, (3) overt and damaging fighting intended to both subdue and injure the opponent. All three forms of fighting are involved in the establishment and maintenance of relative social dominance between individuals sharing the same home territory.

Most dogs sharing the same household establish remarkably stable dominance relations, needing only infrequent dominance threats and ritualized quarrels to maintain the status quo. Even so, fighting between resident dogs is a common complaint. The causes for such fighting are complicated and varied. Some authorities have speculated that the primary cause of instability is owner interference (Hart and Hart, 1985). In such cases, owners may feel sorry for the subordinate "underdog," which they may feel obligated to protect from the "bullying" dominant dog. This protective role may include punishing the more dominant dog while pouring affectionate consolation and comfort onto the subordinate. From the perspective of the combatants, it appears as though the meddling owner is taking sides, perhaps conspiring with the subordinate to overturn the dominant dog's position. The effect of such extraneous interference not only narrows the relative social status existing between the dogs, it may destabilize the situation and set off serious dominance contests whenever the owner is present (Hart, 1977). The owner's alignment with the subordinate antagonist may gradually forge an unwitting social alliance under which the subordinate is inadvertently encouraged and obliged to challenge the dominant dog's authority, at least whenever the owner is present. On the other hand, the dominant dog may progressively *feel* uncertain about the turn of events and shore up its compromised position by resorting to more frequent and damaging attacks, potentially resulting in serious injury to both the misled upstart and the interfering owner. Under such destabilized conditions, what began as a rare ritualized contest over dominance may develop into a serious pattern of escalating aggression between the dogs. Since such contests are never allowed to run a natural course, hostilities are kept at a high pitch of readiness, with the potential for an outbreak of fighting whenever the combatants meet in the presence of the owner. Because overt aggression invariably causes both combatants discomfort, they may, over the course of several fights, begin to view each other as conditioned aversive stimuli. Aversion, the close cousin of fear, causes the combatants to lose aggression-inhibiting affection for one another, further disinhibiting aggressive hostilities and setting the stage for injurious and potentially deadly fights. It is interesting to note that such dogs rarely fight when left alone, but this cannot be relied on in every case, especially where a high degree of interactive tension is present and where a history of serious fighting already exists. As part of their treatment program, some authorities have recommended leaving resident aggressors together when the owner is

absent (McKeown and Luescher, 1988), based on a questionable assumption that such dogs will not fight in the owner's absence. Besides the significant risk involved when the owner returns to potentially aggressive dogs vying for attention, resident combatants do occasionally fight when the owner is absent. Sherman and colleagues (1996), for example, found that 12 pairs of dogs (N = 73 cases) involved in household fighting fought at least one time during the owner's absence. Leaving resident aggressors alone together may result in very serious injury, so the practice should be avoided.

PREVENTION

Many breeds appear to be naturally preadapted to live in peaceful coexistence with other dogs and require little socialization to prevent problems. As previously noted, however, some dogs (especially the traditional fighting breeds) appear to be preadapted to *show* aggression toward other dogs as they mature and may require intensive socialization and training to gain control over their aggressive propensities. For these dogs, the appearance of another male dog represents a powerful releasing signal, triggering a very intense aggressive response. Further, although such behavior can be controlled through training, such dogs may never be completely trustworthy around other dogs.

The most important function of socialization for puppies is to encourage the development of repertoire of playful competitive behaviors. Aggressive play is composed of noninjurious agonistic sequences and species-typical cutoff, threat, and appeasement displays, with which dogs learn how to compromise, control, or defer to an opponent without aggression. Through such interaction, puppies learn that competition does not necessarily result in aggressive conflict. In addition to contact with other puppies, thoughtful efforts should also be made to expose puppies safely to other dogs of various ages. Exposure, however, is not enough to ensure a beneficial result. Socialization is a two-edged learning process and, depending on the sort of interaction involved, can result in either a positive or a negative outcome. Obviously, the benefit or damage produced by socialization depends on the sort of things that happen to puppies while they are exposed to other dogs. Socialization efforts can either lead to greater trust and security or result in increased mistrust and aggressiveness. A puppy should be exposed to other dogs under various environmental conditions and at various locations, but these encounters should always be carefully controlled and supervised. Unfortunately, in uncontrolled situations (e.g., the dog park), the threat of an all-out attack by a poorly socialized and aggressive dog is always possible. Some adult dogs are grossly disorganized in the way they play, whereas others are simply intolerant of puppies; in either case, such exposure may exert a lasting adverse impression on a puppy's attitude toward other dogs.

PART 2: TERRITORIAL DEFENSE

The concepts of territory and territorial defense are commonly appealed to in order to help explain certain forms of canine aggression. Defining precisely what territory is and in what sense a dog defends it is highly problematic, however. Some authors have entirely rejected the construct of territoriality. Moyer (1976), for example, writes,

> The definitions of territorial aggression frequently infer unobservable, anthropomorphic motivational states. These motivational states are projected to the animal and treated as though they were established observations. Territoriality has come to refer to a complex of diverse behavior patterns that vary widely across animal species and within species depending on the animal's sex, the characteristics of the intruder, the season of the year, the developmental stages of the animal, as well as a variety of environmental variables. (226)

The expression of territorial defense varies considerably among animal species, and there is little consensus about what *territory* actually means. The most generally accepted construct of territory is *a defended area.* A difficulty with this definition involves how one can reasonably differentiate territorial defense from protective aggression (Askew, 1996). Borchelt (1983) suggests that the term *protective* is

more descriptive and useful than the notion of territorial defense. He argues that dogs aggressively protect household members (humans and other dogs)—not a territory. Although the concept of protectiveness may solve some problems, Borchelt does not explain how one can be sure that the dog is specifically motivated to protect *others,* rather than simply responding to species-typical threat triggers, such as unfamiliarity or unwelcome approach-proximity (a territorial dimension). One way to test the hypothesis is to challenge the dog in the presence of a stranger or when alone. If the dog responds aggressively, it diminishes the likelihood that it is doing so to protect others belonging to the household. In any case, all protective aggression occurs within some *territorial* frame of reference—a given that is consistent with the *defended area* construct of territory. One way of analyzing how territorial defense and protectiveness may be related to each other is by appealing to distal and proximal causes. Intrusion upon territory may elicit preparatory aggressive arousal (distal influence), whereas close approach-proximity (proximal influence) may evoke a consummatory aggressive response. According to this analysis, intrusion upon territory represents an establishing operation making aggression more likely to occur and, should it occur, result in reinforcement if the intruder is expelled as the result of the aggressive action.

Self-defense and group-defense seem to be inextricably bound up with the defense of territory, that is, the space occupied by the group. After all, without the existence of a territory there is no place for the group to exist and, vice versa, without a group there is no territory to defend. Even the individual animal needs to *claim* a personal space and defend it against intrusion in order to maintain its safety and security. On a most basic level, territory and group defense cannot be adequately understood without reference to the other—the group and the territory within which it exists are mutually dependent constructs, just as the description of a circle depends on reference to both its perimeter and area. In some sense, the decision to emphasize territorial versus social variables depends on the focus of one's analysis. However, what is needed is an integrated analysis—a kind of behavioral geometry that simultaneously addresses both social and territorial variables. Social competition and territorial defense may operate within a single matrix of control-seeking vectors extending over both social (vertical) and territorial (horizontal) space. Among wolves, for instance, this territorial responsibility falls on the alpha and his deputies. When a breech in the territorial integrity of the pack occurs, it is the alpha that leads the defense and engages the intruding interloper; although lower-ranking members may participate in the rout, it is the alpha that is clearly in charge and leading the way.

Control-vector Analysis of Territory

Need Tensions and Control-vector Analysis

On a very fundamental level, all behavior exhibits the character of spatiotemporal directionality; that is, behavior possesses both temporal sequentiality (e.g., attention-intention-action) and orderly spatial points of reference (e.g., sees bird flying by, physically orients toward it, and finally jumps at the bird). Within this context, motivational interests may be conceptualized as need tensions, having particular goals or target objectives located within the animal's local space. To obtain goal satisfaction through the acquisition of these target objectives, an animal must change or control the environment in some way. Need tensions, in combination with their specific target objectives, form control-seeking vectors of variable magnitude that behaviorally converge upon relevant resources, places, and activities located in the environment [see Lewin (1936)]. The sum area containing these various resources, places, and activities represents an animal's social and territorial space. One way of understanding aggression is to analyze it in terms of competing control vectors belonging to *outsider* and *insider* conspecifics conflicting or colliding with each other over the same target resource. The group's living space is defended by deflecting, displacing, or destroying outsider control-seeking vectors that threaten its social and territorial space. Such defense not only protects the integrity of the group's space, it also preserves and reinforces the more or less stable

control-vector relations or *politics* operating within the group itself.

Control vectors are not only characterized by having directionality associated with need tensions, they also possess physiobehavioral properties such as inertia, momentum, velocity, and force. The probable outcome of conflict between two competing control vectors depends on the combined power of these properties exhibited by competitors. In other words, a more forceful control vector, exhibiting a high degree of momentum and velocity, will certainly deflect or displace a control vector possessing less-powerful vector properties. Control vectors possessing the same power vying over the same location or resource will result in momentary unstable equilibrium. Under the influence of growing levels of destabilizing anxiety and frustration, however, unstable equilibrium between competitors may result in one of four possible outcomes: (1) attack-fight (competitor displaced with potential for injury), (2) attack-retreat (competitor displaced with no injury), (3) cutoff or *lateral escape* (simultaneous deflection of both control vectors), or (4) threat-appeasement (competitor deflected from location or resource) (Figure 7.1). Under the influence of increased anxiety (reduced appetitive need tension) unstable equilibrium is most likely to result in lateral escape or appeasement, whereas under the increasing influence of frustration (enhanced appetitive need tension) overt combat is more likely to occur.

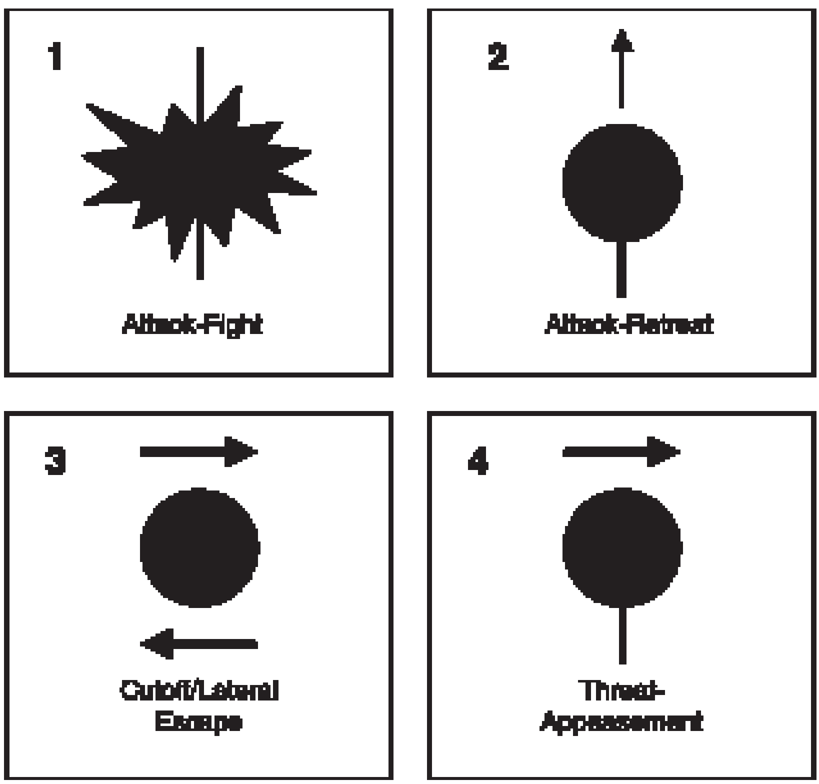

FIG. 7.1. Various control-vector conflict outcomes. **(1)** Equal control-vector magnitudes and need tensions under the influence of frustration over the same resource, with the result of attack and fight. **(2)** Control vectors of unequal magnitude but with equal need tensions converging on the same resource, resulting in attack and retreat. **(3 and 4)** Outcomes of unstable equilibrium (control vectors exhibiting equal magnitude and need tensions) under the influence of mutual anxiety (3) and increasing anxiety (4, *top arrow*) and increasing frustration (4, *bottom arrow*).

Horizontal and Vertical Organization of Social Space

Potentially disruptive interaction between group members exhibiting competitive control-seeking vectors is allayed by the exchange of ritualized threat-appeasement displays—displays designed to maintain adequate distance between *insiders* on both vertical (dominance hierarchy) and horizontal (personal living space) axes of social space (Figure 7.2). The center of territory for a domestic dog is within the home, presumably located precisely where the dog habitually rests or sleeps. At this central zone, the vertical social distancing effects of relative social status are most evident and potentially troublesome. As the result of organizing both horizontal and vertical aspects of group space, serious competition between insiders and their various control-seeking vectors is mitigated. According to this analysis, deference occurs when one individual's control-seeking vectors yield to the control-

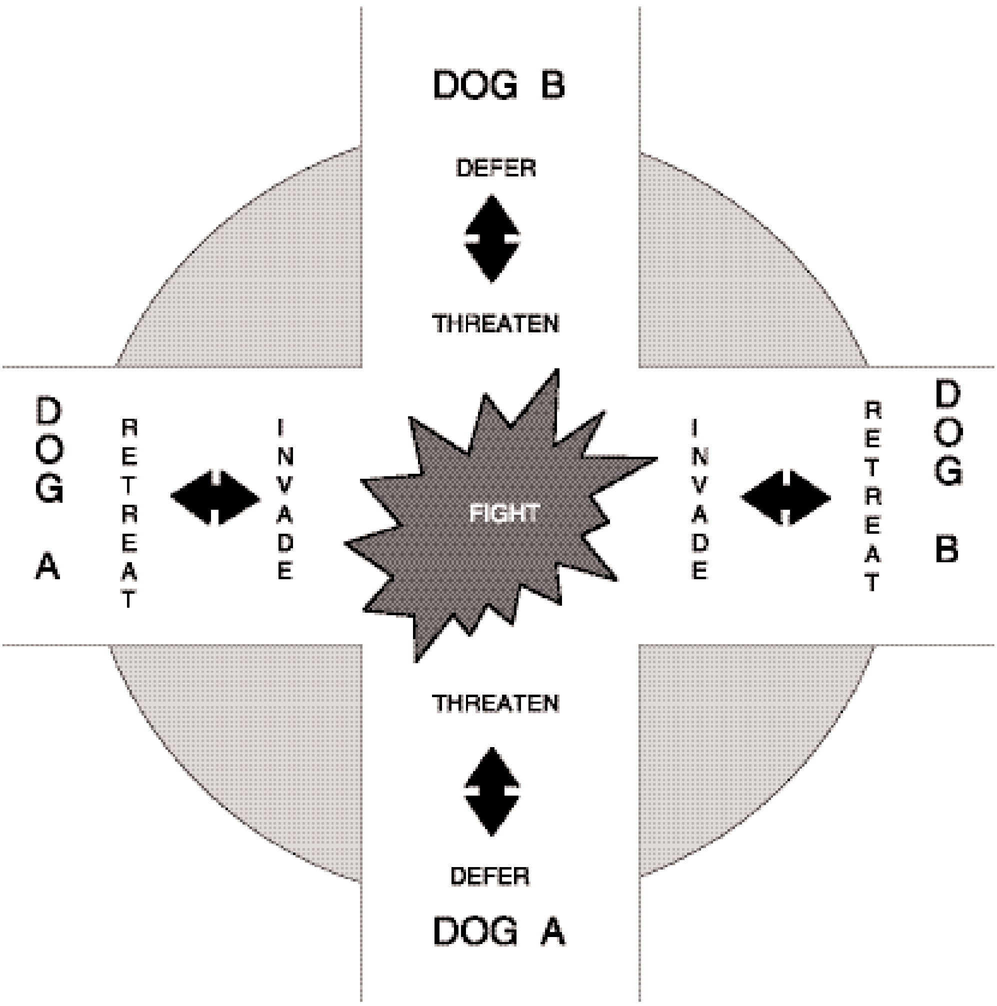

FIG. 7.2. The social space and interaction of a dyad over some common resource. The *vertical axis* of the cross represents the dominance hierarchy, and the *horizontal axis* represents territorial and personal space imperatives. Note that aggression is most likely to occur when both dog A and dog B are simultaneously threatening each other over the same resource or location.

seeking vectors of another by virtue of cooperation (alliance), deflection (ritual threat), or displacement (attack). The *dominant* leader, or alpha, can assert control-seeking vectors in any direction along both vertical and horizontal axes of the group's social space, while yielding to none.

Calhoun's Rat Universe

Of interest with respect to the foregoing vector analysis of territory and social organization are the experimental population ecology studies of Calhoun (1962) [see also Papero (1990)]. In one study, Calhoun captured wild rats and housed them in large enclosures or *universes* with access to unlimited food and protection against predation. Under protected conditions in which unlimited food was provided and predation prevented, he hypothesized that growth rates would be significantly inhibited as the result of social interaction developing under such conditions of abundance and safety. Calhoun made several important discoveries with respect to the development of territory and anomalous social behavior emerging under the influence of adverse environmental conditions. As the population of rats grew, more dominant individuals (corresponding to insiders) took up residency in one quadrant of the habitat, where they eventually established highly stable territories among themselves. As the population of this quadrant increased, weaker individuals (outsiders) were driven out and forced to migrate into other areas of the habitat. These migrant rats were typically low-ranking males. Over time, large numbers of these migrant males formed a colony quadrant of their own. Although more than enough food was provided to feed all the rats, the more dominant rats seized and protected the food, forcing the lower-ranking migrant males to *steal* opportunities to eat while the dominant males were either absent or sleeping.

In contrast to the more orderly quadrant belonging to high-ranking insider rats, the quadrant occupied by low-ranking outsiders was highly chaotic, with no individual rats being able to establish a viable territory of their own. As a result, the few females living in this quadrant were unable to breed and reproduce successfully. When in estrus, females were hounded by packs of male rats, all of whom made efforts to mount and copulate. Calhoun estimated that a female in estrus might be mounted as many as 1000 times in a single night. As a result, such females appeared highly stressed and were much less able to conceive and raise healthy rat pups. This picture was in sharp contrast to the high-ranking females living within the more orderly quadrant controlled by insider males. Under the protection of dominant insider males, insider females were better able to reproduce successfully and raise their young within the security of well-defended territories. Even though the enclosure was large enough to support as many as 5000 rats, Calhoun found at the conclusion of the study that only 150 rats had survived.

Detailing all of the ways in which control-vector analysis might be used to explain Calhoun's findings is not within the immediate scope of the present discussion, but a few points of convergence and interest should be emphasized. Theoretically, when control-vector conflicts reach a density that the group space can no longer support them, the group may experience general unrest and break up into *insider* and *outsider* subgroups, with each exhibiting their own internal and external control-seeking vectors. In the case of Calhoun's rat colony, only the insider rats developed a territory that was defended against the intrusion of outsiders. Even though there was more than enough food available for both insiders and outsiders, the stronger control-vector magnitudes of dominant insiders deflected or displaced outsiders from the common feeding area. Also, it is interesting that the outsiders were unable to form stable control-vector relations among themselves (dominance relations). This failure may have been due to their inability to control access to food and, most importantly, establish and defend nesting areas. The nesting area is presumably the center of territory and the point where vertical social space is first organized as the result of littermate interactions among themselves and the mother. Without a stable horizontal living space and central nesting area, the organization of vertical social space into stable dominant-subordinate status rela-

tions is not possible. Further, without the organization of stable status relations between dominant individuals and subordinates, there is little chance of forming territories within which productive nesting sites might be possible.

How Territory Is Established and Defended

Despite Moyer's misgivings, the concepts of territory and territorial defense remain useful empirical and heuristic constructs for understanding certain aspects of dog behavior. Besides overt territorial-group defense, dogs exhibit other habits that seem intended to communicate both social and territorial messages (e.g., urine marking and alarm or threat barking), perhaps advertising the group's presence or denoting some territorial implication, such as a warning to intruders that the area is occupied. Further, although group protection is undoubtedly a significant variable motivating territorial defense, many dogs exhibit intense aggressive arousal at doors, property boundaries, when chained, or when otherwise exposed to trigger situations presumably related to territory, whether the group is present or not. These observations suggest that the violation of territory in some way triggers or potentiates aggressive behavior independently of the presence or absence of a group to protect. Perhaps the violation of territorial boundaries functions as an establishing operation, preparing a dog to act effectively in defense of itself or its social group.

The propensity to defend personal space and surrounding territory against intrusion by outside conspecifics is a very common feature shared by a great many animal species. This so-called *territorial imperative* is grounded on several ecological and survival needs: resource conservation, population control and dispersion, reproductive needs, group protection, and social unity. The maintenance of territory involves several sensory modalities and methods of communication. Perhaps the most familiar forms of territorial advertisement among dogs are scratching earth, urine marking, and barking. Although territory is an area that is aggressively defended against intrusion, the ultimate function of territory may be to reduce aggression between competing conspecific groups. The establishment and defense of territory appear to parallel the aggression-reducing effects of status established among individuals sharing the same territory. Among most territorial species, the usual targets of territorial defense are conspecifics of the same sex, but other species may also be the object of attack. Even though the same sexes may share a territory by belonging to the same group, they do so by the establishment of vertical space, that is, the formation of a dominance hierarchy. In conjunction, territorial advertisements and dominance displays serve to reduce actual fighting between conspecific outsiders and conspecific insiders, respectively. The evolutionary success of territorial behavior is evidenced by its wide phylogenetic distribution and the tremendous variability that it presents from species to species (Klopfer, 1969).

Urine-marking Behavior

The habit of urine marking appears to be intensely engrossing, especially for socially dominant or aggressive dogs. Many dogs spend their entire walk outdoors doing little more than performing this intriguing ritual. Although primarily a male prerogative, females may also urine mark in a malelike fashion but rarely do so upon vertical surfaces, as is the common habit of male dogs. Mature dogs, like wolves, urine mark conspicuous objects by lifting and crooking their rear leg before squirting a small amount of urine onto a suitable object. Although this method of depositing urine is the most common, other variations are also used (see Figure 9.1), including a modified squatting form where dogs crouch slightly downward with one leg turned outward or slightly elevated (Anisko, 1976).

Urine-marking behavior is usually preceded by olfactory investigation of previously marked areas. At least one apparent motivation for this behavior is to identify and overmark areas scented by intruders. Many dogs lick the area being investigated, perhaps, to "freshen" it for closer scrutiny or to introduce a sample of it into the vomeronasal organ for

pheromonal analysis [see *Vomeronasal Organ (VNO)* in Volume 1, Chapter 4]. Occasionally, when a site proves particularly interesting, a dog may exhibit a flehmenlike behavior known as *tonguing* in which the tongue is rapidly and repeatedly pushed up against the roof of the mouth. Tonguing is sometimes associated with chattering teeth and profuse foaming of the mouth. After marking, many dogs make conspicuous scratching movements with their front and rear feet. These movements not only scar the ground but also cast dirt and debris several feet behind the marker, perhaps imbuing the material with identifying odors from scent glands located in the feet. It has been speculated that such scratching is done to spread the odor of urine, but this is not convincing, since the urine mark is rarely disturbed by the action. A more plausible explanation for the behavior is that it may serve to augment and amplify the scent mark visually, thereby providing additional clues and information about the marker's size, weight, state of health, general vigor, and other such details not readily exacted from the scent mark alone. Fox (1971) notes that such scratching is particularly likely when the dog is aggressively aroused by the presence of a strange dog.

Urine Marking and Territory

One theory of urine-marking behavior is that it helps to space aggressive individuals, thereby reducing competition over limited resources or mates. According to this general notion, chemosensory cues are integrated with other socially significant signals serving various roles in the regulation (e.g., increase, decrease, or maintain) of social distance between individuals and between conspecific groups. Dogs, in general, do not avoid areas marked by other dogs, although it would not be surprising in the case of particularly aggressive dogs to find some avoidance exhibited by dogs that had been previously attacked or worried by the urine marker. The urine-marking behavior of dogs often involves marking over previously established scent marks—a habit that appears to be highly provocative in its own right.

According to Anisko (1976), odors associated with urine marking may play a significant role in "the establishment and maintenance of dominance hierarchies and pair bonds, thereby stabilizing social organization" (291–292). Marking by urinating near or over areas previously visited by other dogs may function to secure or dominate the olfactory environment. An active social interchange results from the activity—a kind of urinary challenge and personal advertisement of the marker's presence. According to Bekoff (1979), the most likely time for a male dog to mark is after observing another dog marking. Socially dominant dogs appear to mark much more frequently than subordinate ones. Dunbar and Carmichael (1981) also found that male dogs are especially attracted to the urine deposits of other male dogs (especially strangers), tending to urinate more frequently on areas marked by dogs unfamiliar to them.

Although a great deal of speculation attributes a territorial function to urinary-scent marking by dogs, the empirical evidence is scant and conflicting. Many authorities have disputed the value of urine-marking behavior for establishing territory by dogs (Scott, 1967; Bekoff, 1979). Voith and Borchelt (1985) succinctly state the case against attributing a territorial function to urine-marking behavior:

> The term *marking behavior* is often used with the implication that it is territorial. This presumption elicits several problems. In the animal behavior literature, territorial behavior denotes defense of a well demarcated area. The relationship between territoriality and marking in dogs as well as many other animals is unclear. Many animals, particularly dogs, do not limit their marking behavior to their territorial boundaries. They mark multiple locations within the territory as well as areas other than the territory. Additionally, scent marking does not keep other animals out of territories. Dogs typically enter other dogs' territories to urine mark. (540)

Evidence for a Territorial Function of Urine-marking Behavior

Actually, some field evidence does support the notion that urinary-scent marking may play a functional role in the establishment of territo-

rial boundaries consistent with the aforementioned rather stringent criteria, at least in some populations of dogs. For example, Tinbergen (1951/1969, 1958/1969) made ethological observations of huskies in Greenland that support the notion that dogs do establish and defend stable territories. Huskies belonging to small pack groups consisting of 5 to 10 members communally defend and drive off intruders. They are also purported to have an "exact and detailed knowledge" of the extent of their neighbors' home territories and avoid areas where attacks are likely occur:

> The most interesting aspect of their behaviour was the fact that these packs defended group territories. All members of a pack joined in fighting other dogs off, the males being more aggressive than the females. This tendency to join forces when attacking strange dogs was the more striking since within each pack relations were far from friendly. . .. The clashes between neighboring packs were extremely interesting to watch. If they met at the boundary between their two territories, where the issues were even, neither group attacked. The males, and more particularly the leaders, growled at each other, and every now and then they lifted a leg and urinated—"planting a scent flag" as it can be called, for this is a means of staking out a territory and advertising it by smell. The state of tension in these strongly aroused, yet inhibited, champions also showed itself in acts which, in their similarity to human behaviour, were a source of endless amusement to us: they took it out on their own pack and the unfortunate dog of low rank who happened to come too near was growled at, or even severely mauled. (1958/1969:30–31)

In addition, Tinbergen found that young huskies did not participate in territorial disputes. Prepubertal dogs appear to lack a concept of territoriality, frequently violating neighboring areas defended by other huskies in spite of their harsh reprisals. Further, the dogs appear unable to learn where they can safely go and cannot go. Tinbergen (1951/1969) comments that "their stupidity in this respect is amazing" (150). As they reach sexual maturity at approximately 8 months of age, they appear to immediately understand, recognizing the topography of surrounding territories, and thereby learn to avoid attacks. He observed in the case of two dogs that several significant developmental changes took place within the course of 1 week, including the first copulation, first active defense of territory, and first avoidance of strange territory. These cumulative field observations seem to give credible support to the notion that dogs—given sufficient opportunity—establish and defend territorial boundaries.

Studies of stray and feral dog populations also suggest that dogs do establish stable groups and defend territory against intruders. For example, Font (1987), who studied a group of stray dogs in Valencia, Spain, found that stray dogs form stable social affiliations, involving the establishment of a dominance hierarchy and the group-coordinated defense of a communal territory. These observations appear to conflict with earlier findings by Beck (1973), which suggested that urban stray dogs form only loosely defined and temporary group affiliations. More recently, Boitani and colleagues (1996) reported that even more active and wolflike patterns of territorial defense and wariness are exhibited by feral dogs. They describe an incident that strongly suggests that dogs do appreciate the territorial implication of scent marking, at least with respect to the significance of lupine scent marking:

> The presence of wolves may, therefore, be an important factor shaping the dogs' home range and determining its location. . . No dispersal movements were observed, and only few brief excursions outside the usual home range were recorded. We have the impression that the dogs moved as if suddenly attracted by a scent: they went to check out the origin and possibly the nature and consistency of the signal. This impression was reinforced when the dogs went into the northern wolf pack territory at a time wolves are usually in oestrus. The dogs ran into and out of the area without stopping or slowing down, as if aware of the risks of being caught intruding in a wolf area. (238)

Although the role of urine-marking behavior for the establishment of territorial boundaries remains undecided, urine-marking behavior by domestic dogs may have been adapted to serve a more subtle "psychological" function

than the explicit demarcation of territorial boundaries. In particular, urine marking may provide dogs with an enhanced sense of confidence while ranging about the neighborhood, making it more familiar and secure. This notion is supported by the observation that puppies eliminate in familiar areas and, later on, at locations previously marked by their parents (Fox, 1971).

Urinary-scent Marking by Wolves

Although the role of urinary-scent marking by dogs for establishing territory is unclear, the activity does appear to serve a territorial function among free-ranging wolves. Peters and Mech (1975), who studied the scent-marking habits of wolves, concluded that scent marking *probably* does help to define territorial boundaries between neighboring packs. One observation they describe is strikingly similar to the incident reported by Boitani and associates. They saw a group of wolves chasing a deer that the pack had just severely wounded. The deer evaded capture by running into the territory of a neighboring pack. The trailing wolves gave up their chase as the deer moved into the adjacent territory. According to the authors, this behavior was out of keeping with the wolf's normal persistence in the pursuit of wounded prey, thereby suggesting that some territorial mechanism may have been at work. Unfortunately, they do not show how scent-mark identification might have played a vital role in the foregoing case. Other bits of circumstantial and anecdotal evidence (subject to much interpretation) are presented in support of the hypothesis. Surprisingly, even among wolves, the case has not been proven beyond doubt that urinary-scent marking is performed to delineate territorial boundaries. Nonetheless, it does seem reasonable to attribute a significant territorial function to scent marking by wolves.

Other studies investigating scent-marking behavior by wolves have shown that it is strongly influenced by both hormonal and social factors, especially relative social status (Asa et al., 1985). Among captive wolves, only dominant males and dominant females urine mark (with an exception of subordinates that are competing for higher status). Urine-marking postures reflect an individual's relative dominance. Additionally, marking behavior increases seasonally corresponding to periods of increased sexual activity and raised testosterone levels. However, seasonal variations of testosterone levels have little effect on the urine-marking activity of subordinate males, suggesting that social status modulates hormonal influences responsible for mediating the expression of such behavior (Asa et al., 1990).

Barking and Territory

In addition to urine marking, territory may be defended through vocal alarms and threats (acoustic marking). Dogs exhibit various forms of both alarm and threat vocalization as a means to draw attention to, or to ward off, intruders. Not only do auditory signals provide information about the approximate distance and direction of the vocalizer, they also provide biologically significant information about the identity of the sender (Heffner, 1976). A recent study of canine growling suggests that *formants* or frequency patterns contained in a growl may give receivers vital information about the sender as a potential opponent, with smaller and larger dogs producing distinctive auditory formants (Riede and Fitch, 1999). In addition to the size of the opponent, growling variations appear to express important information about the sender's readiness to attack, degree of confidence, or willingness to submit. Whereas low-frequency, broad-band growling is associated with threats, high-frequency whining is most often associated with submission. Social and territorial threat displays incorporate a variety of sensory modalities to help amplify and disambiguate the sender's intention and meaning.

Alarm barking is highly valued by most dog owners but may represent a nuisance to neighbors (Senn and Lewin, 1975). Such barking behavior warns the group of a pending threat, as well as countering the intruder's advances further into the home territory; that is, barking appears to serve a dual territorial and group-defense function. Alarm barking is usually sustained as long as an intruder remains present. It is rhythmically organized

with brief pauses of silence of various lengths apparently used to follow the intruder's movements. A less loud and sustained alarm-barking sequence takes place when a dog is surprised by an outside stimulus that it cannot immediately identify as an intruder. Surprise or startle barking involves low-volume "woof, woof" sounds followed by a brief period of silence and more energetic alarm barking, if warranted. Threat barking frequently develops out of alarm barking, especially in situations in which an intruder continues to advance upon the territory. As barking escalates and becomes more threatening, it takes on a more aggressive and threatening character. Threat barking may be interspersed with bouts of growling, snarling, lunging, or snapping at the intruder. If the intruder continues to advance, the dog may either launch an attack or flee from the situation, perhaps continuing its threat barking from the advantage of a more secure position.

Free-floating Territory

The operative definition of territory is *a defended area.* This definition is neither limited in terms of the size of the area nor is it qualified by the amount of time that the area has been occupied. Accordingly, territory can be either small or large or defended over short or long periods (Immelmann, 1980). Some highly dominant dogs appear to take possession of any area in which they happen to be and will defend it against the intrusion of other dogs or people. When such dogs are first introduced to a new area, they often immediately set out to urine mark the entire perimeter of the area systematically before taking interest in other activities**.** The mere fact of *being* somewhere is sufficient for such dogs to prompt energetic efforts to establish a territorial presence over the area and to defend it against the intrusion of other male dogs and people. A territorial imperative appears to follow or *float* with such dogs, moving fluidly from one place to the next with great ease. Each new area is secured and defended with an equal aggressive tenacity.

Some of the peculiar territorial adaptations (e.g., free-floating territorial defense) and associated hypertrophied behavior patterns (e.g., barking and urine marking) may be the result of artificial pressures placed on dogs during domestication. Under the influence of domestication, natural pressures conducive to the organization of species-typical territorial defensive behavior are absent. Domestic dogs are neither required to hunt for their own food, locate mates, nor rear their young under adverse natural conditions. In fact, not only are dogs unique in that they do not hunt for a living or form lasting pair bonds with their mate, male dogs are the only canids that do not contribute to the care of their progeny. The absence of such pressures as these may help to explain some of the unusual aspects and variations of canine territoriality:

> The term "territorial" aggression is applicable to species in which the actual securing and holding of territory has adaptive advantage. In the domestic dog, the function of this behavior has apparently generalized or been selected to include protection of significant persons in the dog's social unit as well as places in the environment. (Borchelt, 1983:58)

An important effect of domestication is the alteration of behavioral thresholds controlling freeze, flight, and fight responses. Selective breeding has exercised a pronounced influence on the development of breed-specific variations in territorial defense by artificially enhancing or diminishing relevant traits and behavioral thresholds (Price, 1998).

Territorial Aggression versus Group Protection

In practice, it is often difficult to differentiate defensive aggression from territorial aggression (Askew, 1996). One useful way to differentiate defensive aggression from territorial aggression is to determine whether fear is present as a significant motivational variable, and whether behaviors indicative of territorial motivation (e.g., barking and marking) are present or absent. Dogs exhibiting strong territorial aggressive tendencies are typically more assertive and confident. Also, the contexts of aggression are often highly specified, involving other male dogs and unfamiliar

human targets intruding on significant territorial boundaries or areas. Territorial aggression involving a high degree of assertiveness can also be differentiated from defensive aggression by the latter's response to behavioral intervention. Defensive behavior is often highly responsive to behavior modification, whereas assertive territorial aggression may strongly resist training efforts. Territorial aggression and group protection cannot be entirely differentiated, because they are mutually dependent constructs. Group protection is the prerogative of a highly dominant dog that appears to respond to territorial intrusion as an establishing operation for the expression of assertive and threatening behavior toward the intruder. Aggression with respect to the protection of others (e.g., children) may be a generalized form of maternal-paternal aggression.

VARIABLES INFLUENCING TERRITORIAL AGGRESSION

Canine territorial aggression is inextricably entwined with the development and protection of the group's integrity as a social and cooperative unit. Protective behavior both establishes territorial boundaries and sets limits between the group and other conspecifics or people not belonging to it. A number of social and environmental factors facilitate social distancing and influence the character of territorial aggression in dogs. Among the most important of these are frustrative restraint, frequency of territorial violation, social facilitation, crowding, and ambience.

Frustration and Restraint

Confinement in the house, behind a fence, or tied to a chain tends to invigorate territorial behavior. Unlike wolves and feral dogs, a domestic dog's freedom of movement is artificially constrained and limited by both physical and social barriers. Such constraints not only define the boundary of a dog's home territory, they also prevent escape to safety in case of danger. These artificial boundaries are often vigorously defended against intrusion. Under conditions of confinement in which a dog's freedom of movement is constrained, it may feel trapped, vulnerable, frustrated, agitated, and thereby become progressively more and more vigilant and aggressive toward the potential threat of intruding strangers and vagrant dogs. In general, the effect of frustrative restraint is to invigorate or distort the species-typical defensive tendencies present in dogs.

Fences, doors, and windows are particularly problematic, since these barriers simultaneously define a dog's territorial boundary, with the potential intruder located just on the other side, leaving little room for other options to present themselves or develop. Defending what little space is left before the territory is breached becomes critically important for a confined dog, especially if escape is not a viable option. There is no buffer zone or room to negotiate other courses of action under such circumstances of territorial intrusion. This state of affairs is especially problematic for dogs exhibiting relatively low fear thresholds and defensive aggression. The resulting defensive behavior of such dogs is often frenetic, compulsive, and extreme. Under situations in which escape is not possible, fearful dogs possessing a strong tendency to engage in defensive aggression are often highly vigilant and prepared to threaten or attack strangers intruding upon their domain. Aggressive tensions and wariness around disputed boundaries (e.g., doorways and fences) can reach compulsive levels.

Finally, some evidence suggests that frustration over food may increase territorial aggression. Jagoe and Serpell (1996) found that dogs fed after their owners showed significantly more territorial aggression than dogs fed before their owners. Speculating, they attributed this tendency to feeding schedule-induced differences of general arousal. They also noted that making a dog wait may alter its perception of the value of food, perhaps making it more defensive over food when confronted with intruding strangers. These explanations are a bit of a stretch given the limited data presented, but it may be important from a husbandry and preventative perspective to feed dogs *before* rather than after the family eats—in opposition to the advice of some trainers and behav-

ioral counselors regarding the benefits of feeding the dog in a reverse order (Rogerson, 1988; Seksel, 1997). Further, contrary to the opinion of Rogerson about order of feeding, Jagoe and Serpell found no evidence indicating that feeding the dog before the owners ate increased the risk of the dog developing dominance-related aggression.

Effect of Frequent Territorial Intrusion

Dog bites are a common cause of injury to mail carriers, with 2851 of them having been bitten in 1995 (U.S. Postal Service statistic). The daily intrusion of mail *violating* the territorial integrity of the door is often the object of fierce aggression, with the dog attacking and tearing up the mail as it is pushed through the letter slot. The mail carrier's daily "intrusion" upon the dog's home territory may gradually heighten its aggressive efforts into a frenzy. Serious problems have developed out of this perceived intrusion and violation of territory. During such encounters, dogs have crashed through glass windows for the opportunity to attack a mail carrier, even ignoring the chemical-spray deterrents used for defense against such occurrences. Since mail carriers are common targets for territorial aggression (Beck et al., 1975), special precautions should be taken to prevent such aggression from developing. A couple of simple measures often help to prevent or reduce such tensions: (1) let the dog regularly meet and accept treats from the mail carrier, (2) when a mail slot is used have the mail carrier insert a biscuit with the mail for the dog's pleasure, and (3) consistently discourage aggressive displays. In extreme cases, the mail should delivered to a mailbox located some distance away from the front door.

Sources of Territorial Agitation: Fences and Chains

Territorial defensive excesses are often expressed in a compulsive form along fences toward other dogs and passersby. Konrad Lorenz reports a comic incident involving territorial aggression between two dogs *defending the same fence line* (Lorenz, 1954). He describes how these two enthusiastic fence fighters were surprised to discover one day that a portion of their shared fence had been removed for repairs. The two dogs, accustomed to run along the fence carrying on a spirited exchange of threat and counterthreat, found themselves face to face without an intervening barrier between them. After a brief stay of hostilities, the erstwhile combatants broke the lull of bewilderment by retreating back to the part of the fence still standing to continue their battle safely. Unfortunately, this amusing anecdote defines the extreme exception rather than the rule. Most fence fighters would readily welcome the opportunity to engage in actual fighting, often jumping over or digging under fences to do so. In addition, serious attacks have been delivered on innocent children and adults reaching through fences or car windows to pet a dog—attacks that sometimes occur without much warning or indication of the dog's aggressive intentions. Children playing near a fence or in view of a chained dog are common sources of agitation, and measures should be taken to prevent such contact and stimulation. This situation is compounded when children actually tease and taunt a dog. Many cases involving the chasing of bicycles and cars appear to involve similar territorial issues.

The invigoration of aggression by restraint can be seen in an exaggerated form in situations where a dog is habitually restrained on a chain and stake. Some of the most severe and *deadly* canine attacks toward humans have been launched by chained dogs or dogs that have broken free of their chain. Sacks and colleagues (1989) reported that among pet-related mortalities that 28% resulted when a child approached too close to a chained dog. In 36% of these cases, the children were killed after gaining unauthorized access to a fenced area containing the dog. Among stray dogs, 35.7% of the fatal attacks were delivered by a dog that had escaped a fence, pen, or other form of restraint. The following is a typical report:

> HAMILTON, Ohio, Nov. 18 (UPI)—Butler County Animal Shelter officials will determine Monday whether a Siberian husky and a chow will be destroyed for attacking and killing 7-year-old Ethan Fricke.

> The 3-year-old husky and 18-month-old chow killed Fricke at the child's uncle's home in Ross while his parents, and other relatives were attending a Saturday baby shower.
>
> The uncle, Nick Toon, said he warned the boy not to play with the dogs unless an adult was present.
>
> "I tried to explain to him that even though they are friendly, they could hurt him because they are bigger and stronger than he is," Toon told the *Cincinnati Enquirer.*
>
> Sheriff Don Gabbard said the boy was playing alone and went into a fenced area of Toon's backyard where the dogs were chained.
>
> Gabbard said one, or both dogs, bit the child, severing an artery in his neck.
>
> Sheriff's deputies say Fricke died less than one-hour after being attacked.
>
> "If the decision is to destroy them, I will agree with that," Toon said, "But I would like to say to others who own chow dogs that they shouldn't run out and destroy them because of this. A lot of people will say they are vicious, but they are not. This was just an accident."
>
> A service for Fricke was scheduled Wednesday at the Fairfield West Baptist Church.

Moral: A chained, intact, male dog is a statistical menace to public safety.

Social Facilitation and Crowding

Dogs living in communal situations are subject to additional pressures that may intensify territorial defensiveness. A well-know factor augmenting territorial aggression is social facilitation. The mere presence of another dog alters the strength of shared or allelomimetic behavior, including group-coordinated territorial defense. Most dogs are much more aggressive when in companionship with other dogs acting out aggressively. This fact is commonly employed by police and military-dog trainers who frequently agitate dogs in group (line agitation) to build confidence and aggressiveness. Under the influence of social facilitation, dogs tend to intensify their behavioral efforts beyond the magnitudes that they would exhibit if alone. When social facilitation is combined with crowded circumstances, especially involving untrained or poorly socialized dogs, the situation is ripe for the outbreak of frequent and potentially serious displays of territorial aggression. Dogs, unlike other species, appear to accommodate crowded conditions without exhibiting a significant increase in agonistic behavior, especially in circumstances where a stable dominance hierarchy has been established among group members before they are exposed to crowded conditions (Pettijohn et al., 1980).

Ambience

Pettijohn (1978) reported interesting findings concerning the relative effects of various environmental influences on the expression of agonistic behavior among male Telomian dogs. Although not specifically concerned with territorial aggression, the study nonetheless provides obvious environmental management strategies that may have practical implications for manipulating aggressive thresholds. He observed changes in agonistic interaction under the influence of various environmental conditions, including a control room (same as home pen—3.0 × 3.5 meters kept at 21°C), cold room (10°C), bright light (floodlights placed in the corners of the room), dim light (lights turned off and windows covered), and small space (room reduced to 3.0 × 1.8 meters). The dogs were all 7 months of age. He found that the total number of attacks, vocalizations, and retreats were most significantly influenced by the amount of light present in the test situation. Dim light increased agonistic interaction by 32%, whereas bright light decreased it by 28% relative to agonistic behavior occurring under normal lighting conditions. These results are striking and pronounced, but it is unclear how relative light intensity might affect the expression of aggressive behavior.

Stressful exposure to loud and sustained noises may also lower thresholds for the exhibition of offensive aggression, perhaps as the result of increasing irritability. Some dogs appear to have a greater tendency to exhibit aggressive behavior during or immediately after noisy household repairs. Two dogs come to mind where sound stress appears to have played a significant role. In one case, involving an adult male Labrador retriever, workmen used a jackhammer to remove an asphalt driveway. During the 2 days while the work was being done, the dog observed the various activities from the vantage of the front porch

and did not show any signs of agitation or aggression. At the end of the second day, however, when a workman approached the front door, the dog darted at to him and bit him on the leg. In another case, an adult male Labrador mix was left outside in a garden while workmen were occupied grinding down several tree stumps. After several hours, the dog approached and threatened one of the workmen, backing him across the yard with threatening barks and lunges. Neither dog exhibited threatening behavior before or after the aforementioned incidents. As a general rule, when work is being done that produces loud noises, dogs should be kept indoors and insulated from such stimulation.

PART 3: FEAR-RELATED AGGRESSION

Fear and Aggression

Fear is a major motivational factor in the expression and inhibition of aggression. The role of fear is a bit complicated and equivocal, since fear usually inhibits aggression under most circumstances involving moderate levels of fearful arousal. For example, trainers of circus animals, especially those working with large cats, put their lives at risk on the assumption that fear can inhibit aggression. Such training with cracker-whips, blank guns, and various threatening props deliberately serves to evoke and carefully balance the opposing tendencies of flight or fight in such animals. Essentially, such training proceeds to establish control by alternately evoking fear and aggression. Whether flight or attack occurs during such challenges depends on past training and relative thresholds for running away (*flight distance*) or holding ground (*critical distance*). Under conditions of abrupt and intense aversive arousal, both fear and anger may be simultaneously evoked—a potentially lethal circumstance for large-cat trainers. Under such conditions, efforts to suppress aggressive behavior by punishment may not reduce aggression but instead precipitate a spiraling escalation of fear and anger. Such efforts are especially problematic in cases in which dogs lack a safe alternative with which to control the evocative situation.

Fear and Avoidance-motivated Aggression

Fearful territorial defense occurs in situations involving intense threatening arousal that cannot be otherwise escaped, that is, when flight is blocked. When threatened, dogs in such situations attack only as a last resort and then only if their freedom of movement is blocked. Fearful aggression is not employed to defend a territorial boundary but to establish a route of escape from an otherwise inescapable and threatening situation. As a result of successful escape, however, dogs may learn to attack more easily (threshold lowered) in the future under the influence of similar circumstance and territorial triggers. Avoidance-motivated aggression (AMA) develops in situations where a dog has learned that aggression will likely work to control some threatening situation. Although defensive aggression theoretically stands opposite to offensive aggression on the agonistic continuum, AMA is often difficult to distinguish from offensive aggression, especially as the dog becomes progressively confident in its ability to control the threatening situation through aggression. In an important sense, aggression, whether it occurs to secure escape or to defend some resource or area, is motivationally unified under the construct of control. Control-related aggression includes aggression occurring under the influence of escalating adversity that thwarts a dog's ability to control an attractive situation or impedes its ability to escape or avoid an aversive one. In other words, a frustrated or anxious dog may assert itself aggressively to secure or alter a motivationally aversive situation. Interestingly in this regard, defensive and offensive aggression may be alternately present in the same dog. Functionally speaking, most forms of dominance- and fear-related aggression are motivated to establish control over a frustrating or threatening social situation.

Fear and Territorial Aggression

Fear-related aggression is highly directional, situationally specific, often precipitated by a territorial intrusion, and highly predictable. Fear-related aggression often occurs under an inhibitory influence, with the target receiving

ample preliminary signs and threats before an inhibited attack is launched. This feature is frequently lacking in *dominance aggressors,* who may attack without noticeable warning and deliver a hard, *angry* bite. A fearful dog usually attacks in an inhibited and nervous manner, biting only hard enough and long enough to escape the feared situation. The target may be children, adults, or other dogs (frequently without respect to sex), and such attacks occur under a variety of provocative circumstances. Obviously, reducing fear is central to effective behavioral control and modification of fear-related territorial aggression. However, in addition to fear-reduction efforts, fearful aggressors need to learn more constructive ways to control evocative social transactions and territorial transitions without responding aggressively.

A strong association exists between territorial aggression and fear. In fact, fear-related aggression is commonly misinterpreted as territorial aggression. Interestingly, both fear-related and territorial aggression are unaffected by castration (Hopkins et al., 1976), perhaps reflecting a similar motivational substrate shared by the two forms of aggression. Fearful dogs are frequently nervous and reactive during territorial transitions (e.g., meeting guests at the door) or under circumstances in which their personal space is limited or their movements are constrained. Such dogs may engage in sustained, frenetic barking efforts, perhaps while simultaneously backing away from the unwanted advance of guests. A fearful dog's reactions are particularly intense in situations involving close confinement. For example, extreme reactions (e.g., sustained barking, lunging, growling, and air snapping) are commonly observed among such dogs when they are approached while restrained or confined (e.g., in a crate or automobile, or on leash). These dogs are probably more worried about defending themselves than defending their territory, but arbitrarily separating these defensive constructs is not useful. Although a dog may react aggressively to defend itself, the trigger is often related to a threat of territorial intrusion. Identifying these territorial triggers, altering them, or changing the dog's expectations with respect to them are important aspects of the behavioral management of such problems.

Social Competition and Aggression

Animals can be both sociable and aggressive. At first sight the two seem impossible to reconcile, for if a fellow species member can arouse both friendly impulses of attraction and those of repulsion one might expect the result to be insoluble conflict. And it is true that all animals living in closed groups have had to resolve this problem. In order to do so a number of inventions have proved necessary. Among other things, rites that appease and establish bonds had to be evolved. Aggressive animals that live in groups are always busy keeping the peace.

IRENÄUS EIBL-EIBESFELDT, *Love and Hate: The Natural History of Behavior Patterns* (1971)

ASSESSMENT AND IDENTIFICATION

Dominance aggression is often described as the most common behavior problem presented for treatment to behavior specialists and counselors (Landsberg, 1991) (Figure 8.1). Most dogs fitting this category either have threatened or have actually bitten a family member. Dominance-related aggression is generally identified by two criteria present at the time of attack: (1) a perceived threat (e.g., gesture, posture, or contact) and (2) intrusion upon a situation occupied by the dog (e.g., possessions, places, and persons). For example, aggressive attacks may occur when an owner attempts to restrain or punish (vocally or physically) the dog or exhibits challenging postures, dominant-appearing gestures (direct eye contact), or even very subtle or benign actions such as

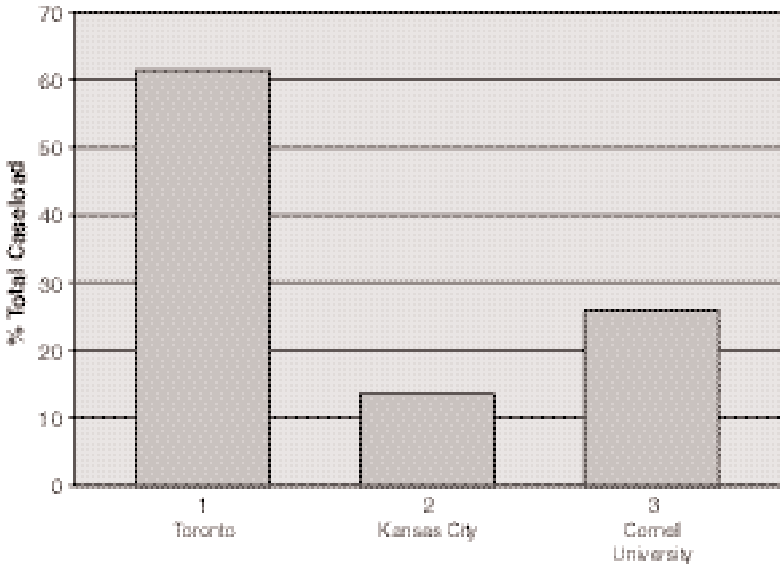

FIG. 8.1. The percentage of cases involving dominance-related aggression for three animal behavior clinics. From Landsberg (1991).

unwelcome petting (contact aversion). Dominance threats or attacks occur under a variety of situations, such as when an owner reaches for toys, food, or other prized possessions located near the dog; when disturbing or attempting to remove the dog from resting areas, especially beds and sofas; when disturbing the dog while in the company of a particular family member (especially when the dog is on the person's lap); and when the dog is put in its crate or the owner attempts to leave the house (Table 8.1).

A distinguishing characteristic of dominance aggression is that it is often situational or object specific and socially selective. For example, it is not uncommon for a dog to be dominant over another dog or family member in one situation but submissive toward them in another. In addition, dogs may exhibit highly selective dominance tendencies, being aggressive, for example, only when in possession of a particular item, while eating, or while in close association with a particular location or person. Aggressive efforts to control a situation appear to be related to motivational factors (biological needs and appetites). Dogs with strong appetitive interests may assert themselves exclusively over food or chew objects, whereas other dogs with strong attachments toward a particular individual may become aroused only when the object of their affection is approached. Still other dogs may become reactive only when their freedom of movement is momentarily constrained, when various parts of their body are physically manipulated, or when intruded upon while resting or sleeping. The selective nature of these arousal situations suggests an underlying differentiation of motivation with respect to those resources and activities. Consequently, treatment programs should address these functional motivational considerations as well as manage coactive emotional influences that may exert pronounced effects on aggression thresholds. These coactive influences and effects on aggression include

1. Frustrative invigoration of appetitive motivation resulting in lowered thresholds for offensive aggression
2. Increased anxious vigilance and lowered thresholds for defensive aggression
3. Increased contact aversion and lowered thresholds for the elicitation of reflexive aggression in response to discomfort or irritability

TABLE 8.1. Control-related dominance aggression: sources of conflict

Situations	Actions
Locations Bed Furniture Sleeping area	Aggression may occur if the dog is disturbed while resting or sleeping. Commonly occurs if the dog is forcefully removed from furniture or a bed.
Doorways	The dog is prompted to move away from the doorway. touched, or stepped over.
Crate	The dog attacks when forcefully placed into a crate or approached while confined.
Rooms	The dog becomes aggressive as the owner enters or leaves the room or house.
Objects Food Prized objects Attachment figure	The dog may become aggressive if approached while eating, chewing, in possession of some prized object, or while in close contact with a family member. Attacks may occur after the dog has been chased into hiding under furniture or when an item is forcefully removed from the dog's mouth.
Tactile stimulation Petting Hugging	In some cases, minimal contact stimulation may evoke a strong aggressive response (low-threshold aggression). Aggressive dogs may not show an affectionate response to petting. They are often aloof and emotionally reserved.
Grooming (e.g., touching ears, feet, nails) Restraint (e.g., lifting, rolling on side, grabbing scruff, clamping muzzle, attempting to put on halter-type collar, forcefully pushing or pulling dog) Punishment	Many of these actions may be perceived as a threat by the dog. It is often difficult to differentiate dominance-related, irritable, fear-related, and avoidance-motivated aggression. All of these forms of aggression fall under the heading of control related and may occur in a variety of situations.
Auditory stimulation Reprimanding Threatening yelling	The dog may become aggressive (snarling or snapping) when yelled at or reprimanded.
Visual stimulation Staring Close eye contact	The dog may become aggressive when stared at—diagnostic for dominance-related aggression. Its pupils may exhibit a reddish glow just before an attack.

After Voith and Borchelt (1982).

Although dogs exhibiting dominance aggression may often defend possessions, not all possessive aggression is motivated by social dominance (Borchelt, 1983; Reisner, 1997). Wright (1980) observed among German shepherd puppies that relative social dominance and competitive (possessive) aggression occurs with some apparent degree of independence, depending on the relative familiarity or unfamiliarity of the situation in which the interaction takes place [see *Social versus Competitive (Possessive) Aggression*]. Among wolves, an otherwise submissive individual may actively defend the possession of food against higher-ranking pack members (Mech, 1970). Mech suggests that possession within an *ownership*

zone of approximately 1 foot from the wolf's nose gives the possessor rights to defend and control the object against intrusion. In an experiment in which an otherwise submissive wolf was given possession of large piece of meat, the subordinate was able to defend its rights of possession aggressively against higher-ranking pack members that had been starved for 72 hours. Interestingly, after eating half of the meat, the subordinate left the prize and, apparently feeling an obligation to appease the alpha pair, alternately approached both of them with abject submissive postures and gestures seeking reconciliation. From the alpha male, he received very severe growling, snapping, and biting, causing the subordinate to fall and roll into a passive-submission posture. From the alpha female, the active-submission behavior produced regurgitation. These events clearly show that possessive aggression may operate under the influence of motivations other than the assertion of social dominance or rank. Consequently, when occurring independently of other forms of dominance aggression, possessive aggression may be more properly understood in terms of defensive motivations rather than offensive ones.

The dominance aggressor commonly exhibits other forms of aggressive behavior, as well, including territorial defense, intermale fighting, and xenopic (toward strangers) aggression. Many dominance aggressors, however, are quite specialized, threatening and attacking only family members. Other dogs exhibiting dominance aggression may threaten or attack guests after an exciting and disarming show of affection and attention-seeking behavior (Reisner, 1997). Some particularly sensitive and reactive dogs possess an extremely low threshold for the exhibition of disproportionate and damaging aggressive attacks. A low-threshold dominance aggressor may attack during benign dominance challenges involving various movements, postures, or intentions perceived by it as dominance or *control* threats. These perceived challenges include bending over the dog, talking to the dog, putting on or taking off the dog's collar, innocuous eye contact with the dog, or simply petting the dog's head or back. Some interesting experimental evidence suggests that a reflexive defensive reaction may be neurologically hardwired and elicited in response to tactile stimulation (Konorski, 1967). Dogs stimulated by an air puff directed into the ear usually exhibited a strong aggressive response toward the apparatus and would attempt to bite the experimenter's hand if it was nearby. Konorski also reported that decorticated dogs exhibited a stereotypic aggressive response whenever they were touched on the back. These findings suggest the existence of a reflexive mechanism mediating aggressive behavior. Perhaps, in normal subjects, such defensive mechanisms are modulated and controlled (inhibited) by higher cortical centers. In the case of some aggressive dogs, these inhibitory mechanisms may be rendered dysfunctional by physical disease or neurotogenesis. This possibility is especially pertinent in those cases involving a sudden increase in irritability and unpredictable attack occurring while the dog is being petted on the head or back, when being talked to at close quarters, or when the victim playfully blows air into its face.

The evaluation of dominant-aggressive dogs, especially those cases involving episodes of sudden onset or unusual signs, ought to include a thorough veterinary examination. This exam commonly includes various blood panels, urinalysis, and fecal evaluation. In areas endemic with Lyme disease, a Lyme test should also be performed. In addition, thyroid function (Michigan State Test) is assessed in some cases involving atypical presenting signs or other indicators suggesting thyroid involvement [e.g., lethargy, obesity, poor coat quality and alopecia, cold intolerance, and avoidance of exercise (tires quickly)]. Thyroid dysfunction has been considered a relatively rare (Reinhard, 1978) or insignificant (Polsky, 1993) factor in the expression of aggression. However, recently it has been suggested that thyroid insufficiency may play a much more important role than had been previously suspected. Aronson (1998) remarks that one reason for the apparent lack of a positive correlation between aggressive behavior and hypothyroidism might be due to the lack of appropriate testing to detect its presence. Not only has she found a clear link between thyroid insufficiency and aggression, she has also implicated a thyroid factor in the expression of a variety of behavior problems, including generalized fear, separation anxiety,

compulsive disorders, hyperactivity, and seizure activity. Although thyroid supplementation may not represent a cure for such problems in hypothyroid patients, it appears to exercise an ameliorative effect:

> While correcting the thyroid imbalance may not provide a complete resolution of the behavior problems, it is an extremely rare animal that shows no improvement, and certainly none shows a deterioration in behavior following treatment. In the future, it is possible that if we test for other endocrine and metabolic parameters, we will discover additional links between systemic conditions and behavior problems. (97)

Some forms of explosive and unpredictable aggressive behavior may be caused by a variety of neuopathologies, including seizure activity (Dodman, 1992). Affected dogs may appear disoriented and exhibit a glazed or deep reddening of the pupils, just before launching into an uninhibited attack. Owners often report that their dogs appear momentarily "possessed" by a paroxysm of aggressive behavior occurring rather independently of identifiable provocation present at the time of attack. Following attacks, dogs may appear dissociated from the event, often acting as though contrite for their behavior. Episodic rage syndrome (sometimes referred to as idiopathic or episodic dyscontrol syndrome) is relatively rare and believed by some authorities to be the result of epileptic seizure activity or damage in limbic areas responsible for the regulaton of aggressive behavior (Voith, 1989). The attacks may occur episodically on a monthly or more frequent basis (Hart and Hart, 1985). Certain breeds appear to exhibit a predisposition for the disorder; English springer spaniels (springer rage syndrome), Bernise mountain dogs, cocker spaniels, St. Bernards, Lhaso apsos, and many other breeds have been reported to exhibit the disorder. Voith (1989) emphasizes the close relationship between unpredictable aggressive attacks and dominance aggression. She notes that such attacks are typically directed toward family members and are provoked under the influence of low levels of stimulation (e.g., petting or ordering the dog to do something). Borchelt and Voith (1985) reported that differential diagnosis can be facilitated by alternately adminisitering epileptogenic and antiepileptic drugs and observing the dog's behavior for aggressive kindling effects or suppression (see *Epilepsy* in Volume 1, Chapter 3). In cases where pathophysiological causes are not identified, episodic attacks would probably be better described and understood in functional terms of *low-threshold dominance aggression* rather than episodic rage syndrome.

The obvious need for accurate diagnostic testing and differential diagnosis of possible underlying disease conditions emphasizes the importance of an active partnership between veterinarians and dog behavior consultants in the resolution of behavior problems. Further, since pharmacological intervention is often employed (especially in severe cases), a consulting veterinarian can prescribe and monitor necessary medications. Ideally, the treatment of dominance aggression should proceed as a team effort, consisting of the client's veterinarian, a consulting veterinary behaviorist, and a professional trainer/behaviorist.

Many authors have emphasized the role of status infringement as a putative cause of dominance aggression, but as will be shown throughout this chapter, what exactly is meant by such notions as social dominance and dominance aggression is far from clear and unambiguous. This is a highly problematic state of affairs, because many of the treatment protocols used to modify this relatively common and dangerous problem are based on assumptions derived from these various theories, especially the belief that treatment efforts should focus on altering a dog's relative status. Unfortunately, however, there is "no convincing evidence" that the usual behavioral treatment programs aimed at reversing the dominance hierarchy actually achieve such changes (Reisner, 1997). Not only are such dogs potentially dangerous, they are also at considerable risk of euthanasia, unless effective behavior modification and training are brought to bear on the problem (Reisner et al., 1994). However, even in cases where appropriate behavior modification is applied, dominance aggression problems are rarely cured. Line and Voith (1986), for example, found that treatment produced some benefit in most dogs (N = 24), but when asked several months later only 1 of 19 dog owners indicated that the aggression problem had been completely suppressed.

CONCEPT OF SOCIAL DOMINANCE

Long ago, Konrad Most (1910/1955) articulated the following influential social-dominance theory of dog aggression:

> In a pack of young dogs fierce fights take place to decide how they are to rank within the pack. And in a pack composed of men and dogs, canine competition for importance in the eyes of the trainer is keen. If this state of affairs is not countered by methods which the canine mind can comprehend, it frequently ends in such animals attacking and seriously injuring not only their trainers, but also other people. As in a pack of dogs, the order of hierarchy in a man and dog combination can only be established by physical force—that is, by an actual struggle in which the man is instantaneously victorious. Such a result can only be brought about by convincing the dog of the absolute physical superiority of the man. (25)

This general theory is familiar to anyone with the most casual exposure to the dog-training literature. Besides the injection of misleading adversarial motivations into the dog's social behavior toward humans, such general explanatory constructions may conceal more by their sweeping generality than they reveal. Such interpretations may also serve to justify inappropriate and abusive training practices. Despite theoretical and empirical problems, Most's dominance theory of aggression is very popular, widely accepted, and sanctified by many respected authorities. In addition, although critical of Most's confrontational philosophy, many contemporary dog behavior consultants embrace the general theory that dogs *normally* form dominance hierarchies among themselves and parallel relations with humans—a system of social organization that determines "which animal has first access to food, resting places, and mates" (Uchida et al., 1997:397). The operative assumption is that dogs view the family as a pack and that they selectively exhibit aggression toward family members, depending on their perceived status. Accordingly, those individuals who are clearly dominant or submissive relative to the dog are believed to be at a significantly reduced risk of suffering an aggressive attack. Only those persons perceived as subordinates and who happen to challenge or confront the dog are at risk of evoking dominance-motivated attacks.

Although the term *dominance* is used with great alacrity and confidence as an explanatory construct, at a most fundamental level there is considerable confusion about what is meant by the idea. How does social dominance or rank order develop? What is the exact relationship between social dominance and aggressive behavior? Are dominance relations between humans and dogs of the same order as dominance relations between dogs? Is attack and threat antecedent necessities for establishing or maintaining social rank? These general questions and others need careful attention and delineation before an adequate understanding of the relationship between dominance and aggression is possible.

DEFINING DOMINANCE

Social dominance is often treated in the literature as a sort of intervening variable or organismic factor, mediating the expression of aggression under the influence of pertinent stimuli and contexts. In the case of dominance aggression, the attack is the dependent variable, and the various stimuli and contextual conditions under which it occurs represent independent variables. The putative intervening variable is *status* infringement. Other authors have variously described dominance in functional terms, as an emergent attribute or merely as a *post hoc* descriptor. Drews (1993) devised the following operational definition of dominance in order to avoid some of the common pitfalls:

> Dominance is an attribute of the pattern of repeated, agonistic interactions between two individuals, characterized by a consistent outcome in favour of the same dyad member and a default yielding response of its opponent rather than escalation. The status of the consistent winner is dominant and that of the loser subordinate. (308)

There is an important distinction being drawn by this definition: dominance is an attribute of a relationship, not an attribute of an individual animal. Indeed, it is hard to

speak of a dog as being dominant, except in relation to some other individual who is subordinate. In other words, dominance is not a personal or biological trait per se but a predictive inference based on a pattern of win-lose contests between two or more animals. The term *dominant* denotes a predictive assumption regarding the most likely outcome of any future competitive event occurring between two contestants. In terms of extremes, the dominance relationship can be termed *rigid* (implying a high probability to any prediction) or *fluid* (implying a low probability to any prediction). Most complex social organizations are structured around a *loose* dominance hierarchy, suggesting that the outcomes of most agonistic encounters are predictable but are not certain. Since dominance is not a trait belonging to an individual, but an *emergent* social attribute arising out of competitive interaction, it is not reasonable to speak of dominance as an inherited trait (Barrette, 1993). Although dominance per se may not be inherited, some characteristics (e.g., size and behavioral thresholds) conducive to competitive success may be heritable.

Many social animals appear to form dominance relations among themselves around situations tending to evoke competition, such as access to food, resting areas, and sexual privileges. For example, if two hungry puppies are presented with a food bowl big enough for only one of them to eat at a time, one of the pair will likely attempt to displace the other by threats or attack (if necessary) to secure exclusive control over the bowl (see *Learning to Compete and Cope* in Volume 1, Chapter 2). During similar future competitive encounters between the two puppies, the loser (now submissive) will tend to yield to the more aggressive winner (now dominant). Among puppies, dominance rank is established through active threats or attack but is subsequently maintained by the mutual exhibition and recognition of species-typical threat and appeasement displays. Social rank order is established to minimize social contests and prevent the outbreak of overt and potentially damaging fighting between competitors, thereby laying a foundation for social order and harmoniously organized group activity (Eibl-Eibesfeldt, 1979).

Structure of Dominance Relations

Schjelderup-Ebbe (1935) performed the first systematic studies of social dominance by observing the social exchanges between domestic chickens [see Wilson (1975) for an historical overview]. Chickens form *despotic* or linear *pecking* orders in which the most dominant chicken or *alpha* can peck at all other chickens without fear of reprisal. Ranked just below the top-ranking chicken in the pecking order is the *beta* chicken, who can peck at any other chicken in the group except the alpha, toward which the beta is subordinate. A similar relationship of dominant-subordinate relations is formed among the remaining individuals until a peck status or rank is assigned to all the chickens involved, with the least-dominant or omega chicken receiving pecks from all other chickens belonging to the group, while being unable to peck at any other chicken within the pecking order. In addition to pecking rights, dominant chickens enjoy various privileges associated with status, such as priority access to food and resting places. Also, dominant cocks exercise a sexual advantage over more subordinate competitors for mating privileges. An interesting finding noted by Schjelderup-Ebbe (1935) was that dominant chickens located further down the pecking order were more aggressive toward subordinates than was the alpha *despot* reigning at the top of the hierarchy. The trend toward reduced hostility in dominant chickens was found to occur when their status was improved after placing them into another flock:

> Often when a bird which ranks low in the pecking order in a flock comes to a higher position in another flock, the bird soon becomes strikingly milder in its conduct. If removed to the flock where it again stands low its harsh treatment of its subordinates once more appears. (963)

The linear pecking order is the simplest way in which a dominance hierarchy is organized within a group, but it is not the only

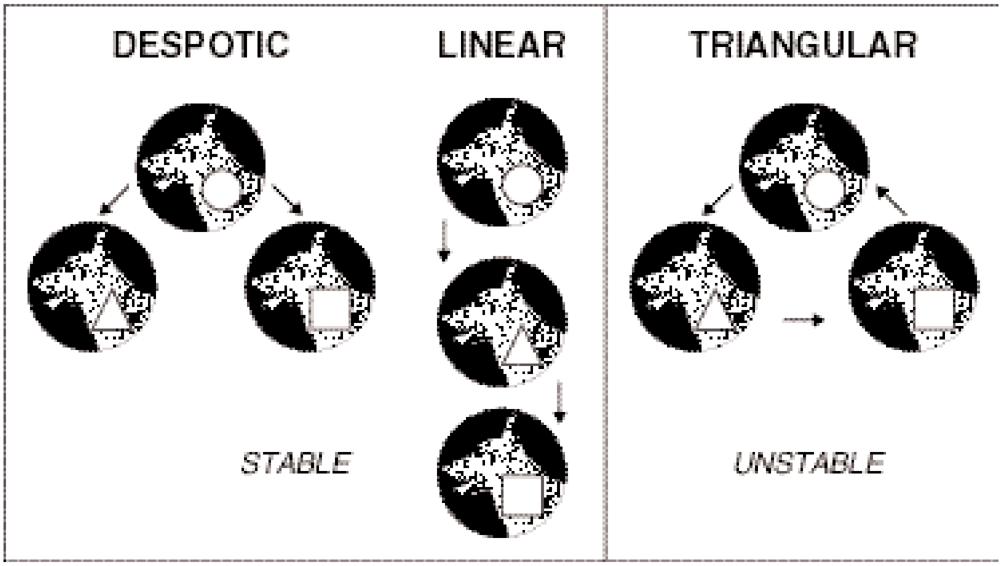

FIG. 8.2. Putative social relations from which dominance hierarchies are organized. Most dominance hierarchies are much more complicated, involving various alliances and contextual influences. After Wilson (1975).

way. In addition to despotic linear structures, triangular and other more complex nonlinear dominance hierarchies exist (Figure 8.2). Among wolves, social ranking is mostly nonlinear in structure (Rabb, 1967; Fox, 1973; Lockwood, 1979) (see *Social Dominance and Aggression*). Instead of a neatly defined hierarchy of status relations based on individual competitive success, wolf-pack social organization is affected by other less obvious *political* factors, such as kinship relations (dependent ranking) and various coalitions exerting pressures on the dominance structure.

In the human family situation, in addition to highly unstable triangular relations, parents may form a cooperative coalition under which influence a dog is subordinate, at least while both are present or when the most dominant of the two is present. However, if the less dominant of the two is left alone with the dog, the dog may assume a more dominant (that is, controlling) role. Frequently, a dog is submissive toward both adults but dominant toward children in the family. Ideally, a family coalition should be formed between the parents and children to secure *rank* over the subordinate dog (Netto et al., 1992). Dogs established midway in the dominance hierarchy (i.e., between adults and children) may behave in a way that parallels Schjelderup-Ebbe's intermediate-ranking chickens, becoming more vigilant and influenced by an enhanced aggressive readiness in relation to *subordinate* family members.

SOCIAL DOMINANCE AND AGGRESSION

To appreciate the role of social dominance as a factor in aggression problems, it is useful to examine some of the ethological findings derived primarily from the study of wolf behavior.

Threat and Appeasement Displays

Both dogs and wolves maintain peaceful social relations by exchanging various species-typical threat (dominant) and appeasement (submissive) displays. Schenkel (1967) has divided submissive displays into two general categories: active and passive. *Active submission* is characterized by increased activity levels and postural diminution, with the tail being carried in a variable carriage and ears held back or twisted in various expressive ways.

Such displays often include active fawning, nuzzling, and licking—*attention-seeking* behavior. Some dogs *grin* or clack their teeth, some may exhibit various pawing motions or crouch down in a play-soliciting bow, and others may crouch with a twist to one side or other, while scooting forward. The tail is often wildly expressive, waving in wide sweeping or whirling motions with the hindquarters moving from side to side. Active-submission displays are observed during greeting between the owner and dog, the dog often jumping up, attempting to push against or lick the returning owner upon his or her mouth—the apparent goal of such behavior (Trumler, 1973). Most so-called attention-seeking behavior by dogs is motivated by active submission. Passive submission is most frequently observed when threats are directed toward the subordinate by the dominant individual. Passive submission involves dramatic reduction of activity (a dog often freezes), averting eye contact, lowering of the head and body onto the ground, and sometimes concluding with a lateral recumbency and exposure of the ventral areas of the chest and the inguinal areas of the abdomen. The ears are pressed back with the tail tucked between the legs. Sometimes, passive submission is associated with submissive urination—an appeasement expression deriving from early reflexive elimination elicited by the mother's lingual stimulation of the anogenital areas (Fox, 1971).

In addition to visual and auditory information, olfactory signals may also play a significant role in communicating social status. Although not yet identified in dogs, releaser pheromones and other sources of olfactory information regulate the expression of aggression and submission in other mammalian species (Sommerville and Broom, 1999). Under intense aversive stimulation, a release of anal sac contents or defecation may occur. Anal secretions may contain chemical or pheromonal alarm signals capable of inhibiting aggression or, perhaps, serving as a chemical-repellent defense aimed at distracting or turning the aggressor away from the attack. Analysis of the pheromonal contents of anal gland secretions [see Preti et al. (1976)] and their various potential effects on canine behavior may be of significant value, especially with respect to potential antiaggression properties. If found to exert such effects, synthetic-scent homologues could be produced that might offer therapeutic as well as practical benefit as humane inhibitors/repellents for the control of aggressive behavior.

Dominance displays involve various threatening gestures and postures. Low-level threats include a dog standing over or assuming an agonistic T orientation toward its owner or another dog. The dog may rest its head over the opponent's shoulders and proceed to ride up on its back before launching into an attack. Some dogs may grab the skin of the neck (scruff) or attempt to control the opponent's muzzle, especially in the case of adult dogs disciplining puppies. Other dominant displays include body bumping and hip slamming, sometimes forceful enough to knock the opponent off its feet. During displays of increasing threat, a dog's center of gravity appears to shift forward with a stiffening of the body and front legs. Characteristically, a dominant dog sets up squarely facing its opponent and maintains direct eye contact or agonistic stare while poised in a state of increasing readiness: ears are up and turned forward, and its body appears swollen as the result of muscular stiffening and piloerection extending from the neck down to the rump. An aggressively aroused dog may appear to walk on its toes, with the tail carried high and its tip rising above the horizontal line of the back. As the threat escalates, the tail may be held stiffly erect or wagged in short rapid arcs. Just before launching into an attack, the dog may exhibit a threatening growl, snarl, widely bare its teeth by retracting the upper lip up and back (defensive display) or by showing an *agonistic pucker* formed by drawing the commissure of the upper and lower lips forward, thereby wrinkling the muzzle and exposing the teeth (offensive display).

Finally, some dogs may exhibit various equivocal or ambiguous signs, such as pawing the owner, leaning on the owner, placing a paw on the owner's foot, mouthing the owner, jumping up in persistent efforts to get up onto the owner's lap, and obnoxious licking efforts in spite of consistent discouragement. These various behaviors are most often associated with active submission or appease-

ment but may be used manipulatively to control the owner—efforts referred to as *obnoxious submissiveness.* Various forms of passive resistance may also be used by dogs in an effort to control the owner's actions. These sorts of behaviors can be problematic to correct with punishment, since by doing so they may become worse. Often a combination of instrumental counterconditioning, extinction, and time-out works well to control such behavioral excesses.

Peace-making Theory of Social Dominance

An important goal of dominance relations and the acceptance of dominant and subordinate roles by group members is the maintenance of group harmony and peace. When Lockwood (1979) performed a factor analysis of behavioral and physical traits correlating with dominance status among wolves, he found that the number of threat displays exhibited by pack members showed a low correlation with respect to relative dominance or rank. In other words, dominant wolves are not distinguished by the overall number of threats they exhibit toward other pack members. Of course, dominant individuals are quite capable of asserting and defending their status but do not lightly flaunt their power or engage in superfluous challenges or troublemaking within the pack. Although the initiation of dominance threats was not a significant measure of social status, several other characteristics and traits were found to be correlated with social rank: a high degree of success at controlling food access, heavy body weight, reception of a large percentage of submissive behavior displayed by conspecifics, and a high frequency of scent-marking activity.

Van Hooff and Wensing (1987) have confirmed many of Lockwood's general findings, observing that the most reliable measure of relative status is postural indicators exhibited by interacting wolves. Dominant wolves present themselves in taller postures relative to subordinates, whereas subordinates present themselves to dominant counterparts in postures that accentuate their smallness. Consistent with Lockwood's observations, Van Hooff and Wensing found that threatening or assaultive behavior was only moderately correlated with dominance, concluding that such behavior may actually belong to a separate behavioral category.

Dominance versus Deference Hierarchy

Although the term *dominance* typically denotes a social relationship based on a regular exchange of species-typical threat and appeasement signals between at least two individuals, the evidence provided by Lockwood and by Van Hooff and Wensing suggests that social rank is not solely or even primarily maintained by threat initiatives exhibited by dominant individuals. For the most part, the dominant animal, or *alpha,* refrains from asserting gratuitous displays of rank, so long as its social priority is recognized and respected by subordinates. Instead of depending on the initiation of threats by the alpha toward subordinates to maintain the group's social hierarchy, such relations appear to be primarily maintained by the deferential active and passive-submission behaviors exhibited by subordinates toward the group leader. Viewed from this perspective, the structure may be more appropriately described as a *deference* hierarchy rather than a dominance hierarchy (Rowell, 1974). According to this notion, the alpha is likely to exhibit dominance threats, only under circumstances in which its status or privileges are disputed, rather than going about unnecessarily challenging and testing subordinate group members. The alpha presumes their subordination, unless they exhibit behavior indicating otherwise. As a general rule, the pack is a peaceful organization, with the highest-ranking individuals being only infrequently involved in serious competitive strafes.

Dominance and Social Harmony

Dog social behavior has often been interpreted and misinterpreted in terms of wolf behavior. Although an alpha wolf is not above an occasional arbitrary assertion of power, a wise lupine leader avoids unnecessary dominance contests and assertions of authority. The establishment of dominance status does not necessarily depend on aggressive competi-

tion. Fonberg (1988), for example, found that dominance is often established without any overt exchange of aggression or obvious physical indications of physical superiority. She notes that dominance established without resorting to aggression appears to be more stable than dominance maintained by constant vigilance and display of strength. Instead of relying on force and threat to maintain control, an alpha's authority depends on other group members actively recognizing and deferring to its status and role as their leader. There appears to be a genuine wisdom in this arrangement, since a more intrusive style of control would run the risk of producing unnecessary and disruptive *dominance tensions* within a group. Also, it is not by accident that so many active and passive-submission behaviors in wolves and dogs are also used to express affection. In fact, submissive displays appear to be a composite of fearful and affectionate elements—belying the affiliative origins of such behavior. Affectionate submission reinforces an alpha's status, makes it feel secure in its position of control, facilitates group cohesion and cooperation, and promotes social contentment and well-being.

An alpha's ritualized expressions of dominance, social distancing, and aloofness all encourage a flow of social affection in its direction, thereby consolidating its leadership by popular opinion. The pack follows its leader, not so much out of fear or compulsion, as from a natural attraction and desire to stay in close proximity with an object of affection. Besides facilitating leadership, affection in wolves and dogs is a natural inhibitor of aggressive behavior. The more affection exhibited by subordinates toward their leader, the more secure, peaceful, and lasting its reign of control is likely to be. Although repeated assertions of dominance may reinforce passive submission, such efforts also close social distance and evoke competitive tensions and fear in subordinates. In situations of high levels of such aggressive interaction, one would expect to observe increased agitation, protest, and a greater likelihood of actual fighting.

As long as dominant-subordinate relations are clear-cut, affectionate harmony will properly characterize the interaction of pack members. Disruptive dominance tensions develop as the result of poor leadership (incompetence) and increased competition between the leader and subordinates. Such competitive interaction has a pronounced influence on the social stability and contentment of the group. Since *only near equals compete,* when excessive competition occurs it signals a narrowing of relative dominance between the leader and subordinates. The direct outcome of competitive interaction is a reduction in affectionate inhibitions and the expression of defiance and aggressive threat by challenging subordinates. During such competitive challenges, the alpha is forced to assert its privilege of rank by escalating aggressive threats toward the disaffected subordinate, which may in turn either submit or counter the alpha's threat with an aggressive counterthreat of its own. At such times, an overt and damaging fight might break out, unless the subordinate submits.

The maintenance of social distance and aloofness plays an important role in the prevention of such tensions. By staying apart and establishing clear symbolic boundaries and limits, an alpha effectively prevents such disruptive agonistic tensions from occurring. When such social boundaries are absent or undefended, the likelihood of competitive tensions and aggression is correspondingly increased. A leader wolf protects its rights and privileges but does not casually intrude on the rights and privileges of subordinates. Even the lowest-ranking subordinate will defend a bone or a piece of food that it has managed to secure for itself. Only a rather incompetent leader would go about challenging and agitating deferential subordinates. In short, the process of maintaining dominance is about regulating social limits and boundaries while making oneself an object of social attention and affection—a leader.

A completely stable group without aggression may not be possible, however. Reportedly, under stable social conditions where agonistic behavior is rarely expressed, aggressive energy may actually *build up* over time, causing the alpha wolf finally, and without much warning or provocation, to attack the omega (lowest) member of the group spontaneously. This sort of aggressive expression has been termed *energy displacement* activity and may represent an adaptive release mechanism controlling the

buildup of aggressive energy, perhaps preventing a more disruptive and damaging outburst (Mech, 1970). This general theory, especially in the form of Lorenz's (1966) *psychohydraulic model* of aggression, has been widely criticized. Lorenz argued that aggression reflected the operation of an underlying instinct or appetite for fighting. According to his theory, aggression is a motivated by a drive similar in nature to hunger and thirst. He believed that *aggressive energy* accumulates over time, eventually compelling the animal to seek a suitable object upon which to *vent* its aggressive energy. If a species-typical object is not available, the animal may express the aggressive energy in the form of vacuum behavior, perhaps attacking under inappropriate situations or displacing it upon inappropriate objects. Lorenz believed that aggressive energy builds up according to the biological needs of the species, causing some animals to show a greater aggressive drive than others. Others have theorized that social aggression is primarily the result of the inevitable frustration that accumulates as the result of interacting with others competing for the same resources or interfering with one's goal-seeking activities. For example, Dollard and colleagues (1939) argued that "aggression is always a consequence of frustration" (1). Frustration is defined by them as any interference in the performance of goal-seeking activity. Calhoun [see Papero (1990)] describes a similar tendency toward an acquired propensity for aggression as the result of social interaction, but interprets it in terms of a need for the attainment of psychobiological balance between frustration and gratification. According to this theory, under social conditions in which an individual receives too many *gratifying* experiences, it will deliberately seek to trigger agonistic episodes to achieve a more satisfying balance between frustration and gratification. Social contentment is achieved by balancing gratifying and frustrating experiences.

Dominance or Pseudodominance

Many authorities have commented on the degenerative effects of domestication on the social behavior of dogs. In comparison to the robust social dominance and submission rituals exhibited by wolves, the corresponding agonistic behavior patterns in dogs have "disintegrated into an assortment of independent behavioral fragments" (Frank and Frank, 1982:519). Although a dog's social reality is strongly influenced by its wolf-genetic heritage, it is hard to describe faithfully the human-dog relationship in terms of the wolf model of social rank. For one thing, the human-dog relationship is often much more equivocal and complex than captured by the concept of social rank. It is also filled with considerable confusion with respect to the meaning of specific social exchanges between people and dogs and how they should be interpreted.

Most social transactions between people and dogs appear to be organized around playful attention-seeking (active submission) exchanges and following patterns, rather than true dominant-subordinate relations based on the purposeful exchange of threat and appeasement (passive submission) displays. Among highly sociable dogs with elevated fear and aggression thresholds, the impulse to challenge their owners for dominance with a sincere threat or contest probably never passes through their minds. Although not feeling very dominant toward their owners, such dogs probably do not feel very submissive or subordinate either. In such cases, the appearance of competitive tension may simply be the net result of frustrating playful exchanges having little ulterior motivation, being nothing more than play for the sake of play and the immediate pleasures produced by the activity. Fun-loving dogs might get themselves into constant trouble as the result of their playful antics and teasing games, become attention-seeking pests, or possibly form an excessively strong attachment with an overly indulgent owner, but such dogs are unlikely to launch a serious dominance challenge against the owner, except in the most playful and obnoxious sense of the word. In such cases, the appearance of social competition is better described as sham or pseudodominance.

Dominance: Status or Control

Aggression directed toward the owner often occurs as the result of competitive or threatening interaction with the dog. Dogs resort to

aggression as a means to establish control over motivationally adverse circumstances generated by the owner. Depending on a dog's success or failure, it may adopt a dominant or subordinate role in relation to its owner and consequently be more likely to threaten or defer to the owner under the influence of similar circumstances in the future. The original causes of aggression are competition or threat, occurring under the influence of loss, discomfort, disturbance, or interference. Under such circumstances, a dog is variably aroused with frustration, anger, or irritability—*establishing operations* that render aggression more likely and provide the motivational bases for its subsequent reinforcement or punishment. If the behavior succeeds, the victim's various gestures, postures, and contact activities present at the time of the attack may be learned as discriminative stimuli controlling future aggressive efforts, especially when the dog is exposed to similar competitive or threatening circumstances. Also, the owner's actions present at the time of attack (approaching, reaching for, or leaning over) may function as conditioned establishing operations (triggers), setting the motivational occasion for the dog to respond aggressively with some expectation of success.

With repeated exposure to such situations, the behavioral thresholds controlling aggression may be lowered, while thresholds regulating the expression of fear may be gradually elevated. These combined motivational influences may cause a dog to become more confident and assertive. As a result, the likelihood of aggression may increase, with its magnitude progressively becoming more vigorous and damaging—all changes occurring as the result of social learning and the alteration of conditioned triggers regulating fear and aggression. If punishment is attempted at such times, the dog's aggressive control efforts may escalate—now intensely invigorated by frustration and rage. If a dog's control efforts are successful, its agonistic behavior may fall under the motivational influence of an additional species-typical incentive: the securement of rank and status. Consequently, the dog may expect its owner to recognize its dominant status and play a submissive role by showing appropriate appeasement and deference behavior in response to its threats. Further, the dog may become progressively intolerant of intrusion (e.g., while sleeping or eating), resent routine control efforts (e.g., grabbing the dog's collar), and react aggressively toward disciplinary actions carried out by its owner.

Dominance aggression often involves very severe attacks that occur under minimal or no apparent provocation at all—characteristics that nicely fit the control-learning hypothesis and analysis of dominance aggression. The notion of *status* is inextricably bound up with learning and conditioning. Although the recognition and display of status appear to play a significant functional role in the organization of dog social behavior and the maintenance of dominant-subordinate relations, most dominance aggression appears to be the result of social confusion, frustration, irritability, contact aversion, and learning. Rather than being socially dominant, many dominance aggressors simply appear to be socially *incompetent* and unable adaptively to navigate the social and interactive demands placed upon them without biting. In the vast majority of cases involving aggression (Borchelt and Voith, 1986, 1996), the behavior appears to be mostly related to control interests, operating under adverse motivational circumstances involving heightened anger, frustration, or irritability. Although there are many situations in which social status may become a significant factor, aggression is primarily grounded upon control-related efforts. Status and status-related aggression come about as the result of a history of success in threatening or attacking the owner. Essentially, status-related aggression is the conditioned outcome of a history of successful aggressive control efforts.

Locus of Control and Social Attention

The nature of social dominance has been analyzed in a variety of ways. A general characteristic of dominance is locus of control, that is, the initiation of significant social activities. Among wolves the leader is usually responsible for initiating and guiding vital group activities, such as hunting sorties, territorial and group protection, and reproduction. A related notion is focus of attention. Dominant animals appear

to attract and control the most attention from group members (Chance, 1967). During greeting displays, for example, the alpha male and female wolf are the object of intense interest and activity. A dog's ability to initiate and control activities and to hold its owner's attention offers interesting possibilities for understanding the notion of pseudodominance. Many pseudodominant dogs express an almost compulsive drive for attention and social recognition. The attention-controlling behaviors involved are frequently of a highly competitive nature (although playful and nonescalating) and are often conflated with hyperactivity. Many of the *games* involved are competitive, involving various taunts and challenges aimed at provoking a response in the owner (Voith, 1980a,b). In many ways, pseudodominant dogs are simply obnoxious subordinates who have not been properly trained to respect appropriate social boundaries.

Schenkel (1967) offers a pithy observation in this regard among wolves: "If the superior is tolerant but fails to display his superiority, the inferior may behave obtrusively" (325). A favorite, rather dominant, attention-controlling game is the familiar "steal a forbidden item and run like hell" routine, thereby evoking an episode of "catch me if you can, stupid" throughout the house. In general, the behaviors involved are designed to maximize the amount and direction of attention toward the dog in a manipulative and controlling mode of interaction. Many other nuisance behaviors fall under this general category, including playful biting at hands and feet, excessive barking, jumping on furniture and guests, pestering antics of various kinds, and other expressions of opportunistic mischief.

Pseudodominant dogs enjoy making a focus of themselves during social encounters and are not adverse to putting on a show for any audience willing to play the role of subordinate *victim.* Dogs that persist in such obtrusive and unwanted behavior, including provocative chase episodes, the initiation of aggressive tug of war games, and rough, uncontrollable play, are expressing a high degree of social competitiveness—a pattern of interaction that may introduce the seed for more serious problems (Netto et al., 1992).

INTERSPECIES SOCIAL DOMINANCE

Harmonious social interaction between people and dogs appears to depend on the establishment of a leader-follower bond. This need is well recognized by most dog behavior authorities and dog owners. A dog's readiness to meet the demands of domestic life is only half provided by its biological predisposition; the other half is provided by the actualizing effects of socialization and training. Without the guidance of a competent leader, a dog's social adjustment may suffer irreparable damage. Although we may sometimes imagine that dogs understand and appreciate our foibles and values, they do not; nor do they appreciate the full consequences of their behavior from our all-too-human perspective. William James (1896/1956) eloquently describes the situation:

> Our dogs, for example, are in our human life but not of it. They witness hourly the outward body of events whose inner meaning cannot, by any possible operation, be revealed to their intelligence,—events in which they themselves often play the cardinal part. My terrier bites a teasing boy, for example, and the father demands damages. The dog may be present at every step of the negotiation, and see the money paid, without an inkling of what it all means, without a suspicion that it has anything to do with him; and he never can know in his natural dog's life. . . In the dog's life we see the world invisible to him because we live in both worlds. In human life, although we only see our world, and his within it yet encompassing both these worlds a still wider world may be there, as unseen by us as our world is by him; and to believe in that world may be the most essential function that our lives in this world have to perform. (57–58)

Konrad Most (1910/1955) echoes these same sentiments:

> We credit him with capacity for thought and with an understanding of human behavior and morality. By introducing the dog into a world which is, in reality, forever closed to him, we prevent ourselves from recognizing the unbridgeable mental gap that exists between man and dog. (3)

As a result of these inherent limitations, a dog's adaptation to domestic life must be con-

stantly guided and shaped by human intervention and training. Suppose for a moment that the relationship was in reverse, and we as infants were cast into the midst of a kindly pack of wolves and somehow managed to survive the ordeal. Consider how confused we would be by their customs and manner of doing things. We would never really have a clue but would nonetheless gradually adjust to the natural contingencies of reward and punishment provided by the situation (or perish). A major difference between a dog's fate and this hypothetical one is that we can serve a dog's interests and assist in its adaptation by becoming a rational proxy for it in this strange world, guiding the dog's choices until it is adequately socialized and trained to make the correct choices on its own. To accept our leadership, a dog must adopt a submissive and cooperative attitude at a very early stage in its development and remain that way for the rest of its life. The majority of dogs appear to defer to human leadership instinctively; all that is needed for success is an owner who embraces his or her responsibility and takes control. A puppy's affectionate and dependent attachment is an expression of its natural inclination to submit to our guidance. A dog's sense of security and well-being depends on its owner recognizing these needs and satisfying them with adequate socialization and training.

Avoiding a persistent "ritualization of confusion" arising from mixed messages and misunderstanding between the owner and dog begins with the establishment of clear and definitive social boundaries. Defining oneself as a leader is accomplished by defending social limits (e.g., not permitting the dog to jump up, to bite on hands or clothing, or to pull on the leash), maintaining appropriate social distance, and developing a cooperative relationship based on gentle compliance training and directive measures, when necessary. As a result of such efforts, the dog will naturally become increasingly affectionate and cooperative. Leaders avoid engaging dogs in unnecessary contests of will, but when their authority is challenged, they provide immediate and definitive actions that leave no room for doubt about where they stand on the matter. On the other hand, leaders recognize and reciprocate cooperation with affection and other attractive consequences. Directive actions are mostly used as a means to defend an infringed social boundary, rather than as a routine means for compelling obedience. Once these necessary preliminaries are settled, instructing a dog becomes an easy and enjoyable task because it is oriented toward the trainer as an affectionate and subordinate follower. Once basic social boundaries are established, other behavioral objectives are rapidly achieved by differentially presenting or omitting rewards, such as affection, food, play, and other activities and resources that the dog may desire to obtain.

Aside from a failure of owners to establish themselves as leaders, dominance-control tensions often evolve as the result of ineffectual disciplinary interaction or interference. As evident by their desire for human contact, most dogs are innately submissive to their owners; even in cases where the owners may fail to play a satisfactory and consistent leadership role, their dogs remain affectionately submissive. But sometimes such neglected dogs may become progressively intolerant and aggressive toward the owner's efforts to control them. Many dominance-related problems appear to stem from dominance tensions produced by the owner's habitual and ineffectual efforts to control the dog's behavior. From an early age onward, dogs are exposed to repeated and ineffectual efforts to control or punish them. The problem is compounded when, failing to secure a dog's compliance, the owner simply gives up or clumsily enforces his or her demands. As a result, the dog may become progressively competitive, resistant, difficult, and intolerant of control. Several other negative side effects may ensue from this pattern of interaction:

1. The owner and dog become locked in a pattern of unresolved competition.
2. The stabilizing social distance between the owner and dog becomes progressively narrowed or obliterated.
3. Unresolved dominance conflicts and tensions increase the dog's frustration and irritability while simultaneously rendering it less submissively affectionate and tolerant toward the owner.

Dominance-control tensions and frustration may accumulate as the result of such interaction, until at last a point is reached where a dog becomes intolerant of its owner's irritating or frustrating interference and infringements on its *space.* As the dog becomes more confident and overtly aggressive, its affection and tolerance for contact with the owner may suffer diminishment, as well. It should be noted, however, that many dominance aggressors are highly affectionate toward their owners and may only become intolerant of contact under the influence of specific situations. Upon reaching social maturity, the dog may become progressively aloof, distant, irritable, and resistant to control. If these attitudinal and behavioral changes are not checked, the dog may come to view its owner's efforts to control it as provocative threats. The dog may resort to aggression in an effort to counter the owner's control efforts and to set social boundaries between itself and its ineffectual owner. If the dog does bite, the aggressive actions are likely to go unpunished. Most owners at this point simply back off in shock, only to return later to *reach* the offending dog with placative bribes of affection and food, thereby making matters worse by playing the affiliative role of the subordinate.

Even more potentially damaging, some owners may attempt to punish the behavior, causing the dog to redouble its aggressive efforts, under the escalating influence of pain, fear, and anger. If the dog succeeds in defending itself or perceives that it has controlled the situation by resorting to aggression, it will tend to resort to such behavior under similar circumstances in the future. To defend itself most effectively, the dog may adopt a highly vigilant attitude and learn to react preemptively to previously neutral stimuli associated with such punitive situations—avoidance-motivated aggression. In addition, internal stimuli associated with such provocative situations may trigger establishing operations that prepare the dog to behave in a threatening manner and raise the likelihood that such behavior will undergo significant reinforcement if it succeeds.

According to the foregoing analysis, the dog exhibits aggression because such behavior succeeds in controlling the owner-target. The intrusive actions of the owner function as conditioned establishing operations, triggering motivational changes conducive to the emission of aggressive behavior and setting the stage to reinforce the aggressive behavior strongly, if it succeeds. Reinforcement occurs when the owner is displaced by threat or attack, simultaneously reducing aversive aggressive arousal and replacing it with emotional relief and elative feelings of enhanced well-being and control.

SOCIAL DISTANCE AND POLARITY

Many dominant-aggressive dogs tend to be rather reserved with their affections, often being affection receivers rather than affection givers. Although affection can be a strong inhibitor of aggression (see below), its inhibitory effect depends on the direction of affection, that is, its *polarity.* The subordinate affection giver is much more inhibited about behaving aggressively toward the dominant object of affection than the dominant affection receiver is toward the giver of affection. Fear toward the object of affection is often irrationally suppressed in the affection giver, as is evident, for instance, in the case of an abusive human relationship involving physical battery. This effect is also present in the persistent affection and lack of appropriate fear exhibited by some owners of dominant-aggressive dogs.

A subordinate is urged on by social attraction to stay in relatively close proximity with the leader, an attraction that may paradoxically increase with repeated exposure to the alpha's threats and subsequent reconciliation. The growing leader-follower bond serves both to reduce the future likelihood that the subordinate will challenge the leader and may simultaneously increase the leader's tolerance for contact with the deferential and affectionate subordinate. In both cases, the risk of aggression is decreased by affection; that is, affection reduces the likelihood that the subordinate will act aggressively toward the leader, while the reception of affection renders

the leader more tolerant of contact with the subordinate. This ideal arrangement of reciprocal inhibition is not always evident, however. Many dominant dogs appear to be intolerant of contact, even affectionate contact. In such cases, increased affectionate interaction does nothing to encourage tolerance but may, on the contrary, increase intolerance. The effect is analogous to unrequited love between humans, where the lovesick suitor persistently seeks the attentions of a lover, even though the efforts are repeatedly scorned and punished. Although affection is normally highly desirable and conducive to tolerance and reciprocation, under such circumstances the persistent efforts of the suitor (affection giver) may become highly aversive to the object of affection.

The direction of social polarity and attention reflects the cumulative outcomes of agonistic and affiliative exchanges, with affection and attention-seeking behavior (active submission) moving primarily from the subordinate toward the alpha. Social polarity, based on affectionate submission, provides the foundation for orderly group cooperation and organized activity. Early social dependency involving the reception of nurturance and protection gives way to more mature social relationships based on emergent social status and the formation of a leader-follower bond. In essence, social polarity provides a motivational substrate for mediating social stratification and organizing leader-follower roles.

Reversing the direction of social polarity through integrated compliance training, whereby the reception of affection and other rewards is made contingent on subordinate behavior, offers a useful management technique in the treatment of dominance aggression. As a preliminary to such training, dominance aggressors are often ignored for several days until they seek out the owner's contact and actively solicit affection—affection that they must now learn to earn (Campbell, 1992). This may be a very hard recommendation to implement by owners who are profoundly attached to their dogs and unwilling to exchange the immediate pleasures of doting affection for the delayed therapeutic benefits of social distance and integrated compliance training, that is, owners who are unable to make themselves leaders worthy of canine affection and respect. The power of the *cold shoulder* for managing dog behavior was first reported by George Romanes (1888). The anecdote describes a Skye terrier that had decided with strong aggressive protests not to accept its bath anymore. The owner of the dog happened upon the strategy of withdrawing affection. The effort took several days, but the dog finally relented and accepted her control:

> "In process of time this aversion increased so much that all the servants I had refused to perform the ablutions, being in terror of doing so from the ferocity the animal evinced on such occasions. I myself did not choose to undertake the office for though the animal was passionately attached to me, such was his horror of the operation, that even I was not safe. Threats, beating, and starving were all of no avail; he still persisted in his obstinacy. At length I hit upon a new device. Leaving him perfectly free, and not curtailing his liberty in any way, I let him know, by taking no notice of him, that he had offended me. He was usually the companion of my walks, but now I refused to let him accompany me. When I returned home I took no notice of his demonstrative welcome, and when he came looking up at me for caresses when I was engaged either in reading or needlework, I deliberately turned my head aside. This state of things continued for about a week or ten days, and the poor animal looked wretched and forlorn. There was evidently a conflict going on within him, which told visibly on his outward appearance. At length one morning he quietly crept up to me and gave me a look which said plainly as any spoken words could have done, I can stand it no longer; I submit. And submit he did quite quietly and patiently to one of the roughest ablutions it had ever been his lot to experience; for by this time he sorely needed it. After it was over he bounded to me with a joyous bark and wag of his tail, saying unmistakably, 'I know all is right now.' He took his place by my side as his right when I went for my walk, and retained from that time his usually glad and joyous expression of countenance. When the period for the next ablution came round the old spirit of obstinacy resumed its sway for a while, but a single look at my averted countenance was sufficient for him, and he again submitted without a murmur. Must there not have been something akin

> to the reasoning faculty in the breast of an animal who could thus for ten days carry on such a struggle?"
>
> This strong effect of silent coldness shows that the loss of affectionate regard caused the terrier more suffering than beating, starving, or even the hated bath; and as many analogous cases might be quoted, I have no hesitation in adducing this one as typical of the craving for affectionate regard which is manifested by sensitive dogs [Romanes's comment]. (440–441)

This nice anecdote underscores the efficacy of affection-attention withdrawal for reversing social polarity and enhancing relative dominance.

Despite the ethological appeal of the social polarity hypothesis, it needs to be stressed that the presence of active affection and solicitation of attention is not necessarily a sure indicator of a dog's intention and the risk of aggression. Some dominance aggressors appear to be highly affectionate and excited about contact, only to bite when the owner handles them in the wrong way. Some may enthusiastically greet visitors with intense displays of apparent affection and attention giving, only to bite them as they become more familiar and they attempt to pet or hug them. Others may make themselves the center of affectionate attention and remain nonaggressive, at least until the visitor (or family member) gets up to leave the house. The role of affection and attachment in dominance aggression is complex, and the foregoing is offered as a tentative hypothesis. Perhaps, dogs that show what appears to be authentic affection and attention giving but, nonetheless, bite under the influence of minimal provocation (e.g., upon being petted) are truly of a sociopathic order. In such a case, attention and affectionate displays may be offered in the absence of sincere submissive intentions and other social implications that one might be given to expect. Like the human sociopathic aggressor, the canine sociopathic aggressor may lack true empathy and feeling and more or less *feign* affection and submissive sociability, thereby concealing an aggressive potential. Interestingly, such dogs are often distinguished by an intolerance for frustration and an inability to engage in fluid *give and take* competitive play.

AFFILIATION AND SOCIAL DOMINANCE

An important aspect of group organization is the exchange of affection and the development of affiliative behavior. In addition to offsetting and balancing tensions generated by competitive interaction, social exchanges involving affectionate behavior encourage group cohesion and identity. The importance and function of affiliative bonding between aggressive group members have been emphasized by Lorenz (1964):

> Indubitably, ritualized aggressive behaviour is at least one root of bond behaviour. . . . There may be other independent ways in which bond behavior has evolved, but wherever it did, it seems to have done so as a means of controlling aggression, that is to say on the basis of aggressive behaviour preexisting. In the Canidae for instance, in the dog-like carnivore, all gestures and ceremonies of greeting, love and friendship are obviously derived from the expression movements denoting infantile submission. . . . The strongest reason, however, which makes me believe that all bond behaviour has evolved, by way of ritualization, on the basis of intraspecific aggression, lies in an unsuspected correlation between both. We do not know, as yet, of a single organism showing bond behaviour while being devoid of aggression; in a way, this is surprising, as, at a superficial appraisal, one would expect bond behaviour to evolve rather in those highly gregarious creatures which, like many fish and birds, live peacefully in large schools or flocks, but this obviously never happens. . . . Also, there seems to be a strong positive correlation between the strength of intraspecific aggression and that of bond behaviour. . . . No more faithful friendship is known in this class than that which S. Wahburn and I. De Voore have shown to exist among wild baboons, while the symbol of all aggression, the wolf, whom Dante calls the "bestia senza pace" has become "man's best friend," and that not on the grounds of properties developed in the course of domestication. (47–48)

Without a strong social bonding tendency and sense of affiliation, reinforced through species-typical socialization patterns and affectionate exchange, the disruptive effects of agonistic interaction would gradually disperse pack members and destroy the family/pack group. In other words, hierarchically organ-

ized animals appear to *love* one another in spite of their ritualized and sometimes fierce competition. Without affection, the social order would rapidly disintegrate into a chaos of disorganized self-interest and individualism. According to Schenkel (1967), among wolves feelings of belonging such as love and intimacy are acquired in the context of forming dominant-subordinate relations:

> There is no doubt that submission is an appeal or effort to friendly social integration, to which the response by the superior is not stereotyped or automatic. Only if the superior, too, is motivated to enter into friendly contact with the inferior, will harmonic social integration really take place. If he responds with non-tolerance, the inferior will not persist in submission. Both components of submission, namely inferiority and "love," can only exist if they meet "generosity," i.e., superiority combined with tolerance or tolerant "love." Both the superiority-inferiority relation and the atmosphere of "love" and intimacy do not rely on automatic responses but are shaped in the social contact as components of "personal" interrelationship. (326)

A representative expression of such group affection is observed in the canid greeting ceremony—an active-submission pattern exhibited by both wolves and dogs. Among dogs, the licking toward the face, presumably done by puppies to elicit regurgitation, is progressively transformed through developmental stages into an appeasement gesture and, ultimately, into a profound expression of canine affection and intimacy.

Affection and Competition

The social behavior of dogs is driven by two antagonistic motivational incentives: affiliation and competition. These complementary interests serve to establish a highly bonded and well-organized family/pack unit. Under normal conditions, these two social motivational systems mutually regulate each other to maintain group order and cohesiveness. In situations where either affiliation or competition oversteps appropriate bounds, one would expect to find corresponding disturbances in the group. For example, without the countervailing effects of affection and affiliative bonding, agonistic behavior would tend to disrupt the normal functioning of the group. Further, in the absence of affection, growing agonistic tensions would gradually disperse group members and destroy the group. Conversely, an excess of affiliative bonding and affectionate restraint would limit beneficial competition, thus preventing the formation of a dominance hierarchy. A group without internal competition and a viable dominance hierarchy would lack effective order, structure, and direction—potentially becoming an amorphous and ineffectual agglomerate of aimless individuals.

An important function of affection and affiliation is to facilitate interactive harmony and tolerance among group members. A few general predictions can be formulated concerning the relative effects of affection and aggression on the organization of canine social behavior. In cases where affectionate bonding is lacking, agonistic behavior should increase along several dimensions. Conversely, as affectionate bonding is rendered more secure and reliable, the incidence of aggressive behavior should correspondingly decrease in frequency and magnitude. Under conditions in which affectionate leader-follower bonding is prominent, one should expect to find increased attention turned toward the owner and a greater willingness for the dog to engage in cooperative behavior. However, in cases where affiliation and affection are conflicted motivationally with excessive frustration and irritability, perhaps as the result of dysfunctional interaction or an absence of leadership, the likelihood of social tension and aggression is increased.

Contact Aversion and Aggression

If affection and affiliative bonding modulate agonistic behavior, how does one explain the appearance of dominance aggression in situations where affectionate interaction between the owner and dog is not lacking? To begin with, although affection giving may foster a strong attachment between the giver-and-receiver dyad, it need not necessarily facilitate affiliative bonding between them (Scott, 1991). Bonding is distinguished from attachment by the presence a shared exchange based on affection, cooperation, and trust. One can

form an object attachment to a place, a thing, or an animal without necessarily forming an affiliative bond with it. A bond implies a two-way exchange, whereas an attachment may form and operate in one direction only. Many dog owners form object attachments with their "pet" dogs but fail to form an adequate bond with them. Gratuitous affection may be highly gratifying for the owner to give but be resented by the receiving dog. In some cases, affectionate overtures by the owner may be received by the dog as tactile agitation and interference, resulting in increased irritability and frustration. In other cases, affectionate interaction may be perceived as a threat or source of discomfort. For example, picking up, hugging, and patting a dog may not be perceived by it as a particularly pleasurable or welcome activity. Further, not all dogs enjoy being petted, especially when the petting is delivered by insensitive and clumsy hands. Although a dog may passively accept unsolicited affection, it may gradually become emotionally distressed and resentful of such contact. Thus, what an owner intends as affection may not be received by the dog as affection at all, but rather experienced as an annoyance—an irritating and frustrating annoyance. As the result of unwelcome affection, such dogs may become progressively intolerant of petting or handling and finally act out aggressively to establish social distance.

In summary, some dogs may resent affectionate contact and only tolerate such interaction under clinched teeth. Unwelcome affection may be a significant source of irritability and frustration for such dogs. According to Panksepp (1998), frustration and anger are closely associated in the psychobiology of animals:

> Is the feeling of frustration really substantially different than that of anger? Psychobiological evidence certainly allows us to conclude that they are intimately linked, since manipulations that reduce the effects of frustration, such as antianxiety agents and temporal lobe damage or more restricted amygdaloid lesions, also tend to reduce emotional aggression. Thus, the emotional feeling of frustration may largely reflect the mild arousal of RAGE circuitry, in the same way that anxiety may reflect weak arousal of FEAR circuitry. (192)

If frustration is experienced by a dog as low-grade rage, over time and repeated exposure, the accumulated frustration and irritability arising from unwelcome social contact may gradually lower relevant rage-response thresholds controlling the expression of overt aggression. A contact-aversion interpretation fits a number of the facts associated with dominance aggression:

1. Aggression is often selectively directed.
2. Aggression often takes place in areas associated with affectionate activity (e.g., on sofas and beds).
3. Aggression often occurs under the influence of minimum stimulation, such as when the dog is being reached for in a nonprovocation way.
4. Aggression is often explosive and inappropriate, suggesting an accumulated tension building up over time.
5. Dominance aggressors may become progressively resentful of affectionate contact and resist efforts to elicit play.

This general situation cannot be resolved by simply providing aggressive dogs with more affection. As already noted, giving such dogs affection may not promote affiliation but may instead generate an opposite effect: increased frustration and irritability. The critical factor is to reverse the social polarity between the owner and dog, so that the dog learns to give attention and affection to the owner, rather then receiving it exclusively from the owner. In an important sense, submissive behavior *is* affectionate behavior. Affectionate physical gestures placate the leader, rendering it more benevolent and forbearing with respect to the subordinate's intrusions. Although directing affection and attention toward a dominant individual may have an aggression-reducing or pacifying effect, directing such affection and attention toward a disaffected subordinate may exert an exactly opposite influence, perhaps, in some cases, disabling *status*-related inhibitors that restrain the subordinate from behaving aggressively toward the dominant figure. In other words, making the subordinate the *object* of affection and attention (engaging in submission behavior toward it) may inher-

ently promote annoyance, resentment, and aggressive arousal in the subordinate—an unexpected effect that may actually promote social disruption and disorganization. For example, under natural conditions, an attention- and affection-giving alpha would eventually disinhibit otherwise submissive subordinates to challenge it for social dominance. An interesting possibility is that affection giving by an alpha may be mildly aversive for it, just as receiving affection from a dominant individual may be annoying for a subordinate. Perhaps love is only possible between social equals—the alpha pair.

Reversing Social Polarity and Establishing Leadership

The etiology of dominance aggression is a complicated cluster of inherited traits (especially behavioral thresholds controlling the expression of fear and aggression) and various actualizing experiential influences, including emergent dominance relations. The usual focus on status and the importance of dominance rank and contests between an aggressor and victim-owner overshadows the vital role of social polarity (direction of affiliative interaction) in its management. As previously described, affiliative interaction between a dog and its owner is commonly conflicted in various ways. Where affiliative bonding is secure and affection mutually shared, the probability of overt aggression is much reduced. However, in situations where the dog's affection toward the owner or vice versa is compromised or conflicted by distrust or resentment (contact aversion), the likelihood of agonistic behavior is much increased. Under the influence of distrust or contact aversion, affectionate interaction between the owner and dog may become the source of considerable tension, perhaps causing the dog to become progressively annoyed, intolerant, and aggressive.

This situation can be beneficially influenced in several ways. First and foremost, in the case of a disaffected subordinate, the direction of social polarity must be reversed, so that affection and attention is directed from the dog toward the owner. As Romanes's anecdote suggests, the withdrawal of attention and affection often exercises a pronounced effect on a dog and its willingness to submit. Requiring a dog to turn its attention actively toward its owner, by withdrawing gratuitous contact and "playing hard to get," offers a viable means for initiating an about-turn in the direction of social polarity. Seeking affection is a step in the right direction toward learning to give it. The owner invites enhanced attention, affection, and other active and passive-submission behaviors by rewarding such activity with highly desirable outcomes. These changes are facilitated by initiating reward-based training activities that possess a high degree of structure, safety (predictability and controllability), and play. Such efforts are designed to promote maximum interactive success while minimizing frustration. As a result of such training activities, the dog learns *how to operate the owner* to satisfy its needs, thereby simultaneously enhancing cooperation, dependency, and submissive tendencies. Furthermore, the dog's success at controlling desirable outcomes by deferring to the owner's contingencies of reinforcement serves to inculcate the notion that cooperation pays off. Interactive success is highly rewarding for both the owner and dog, making the owner a more attractive and effective leader and the dog a more obedient and affectionate follower. Leadership is essential if the owner is to attract the dog's attention, affection, and submission.

An important goal of integrated compliance training is to secure a dog's attention and submission to owner-directed control. As this goal is gradually achieved, the dog learns to defer without resistance or resentment. However, just learning that it can control attractive events is not enough; the dog must also learn that it can control mildly aversive and intrusive ones as well. Physical control and restraint are gradually introduced under highly controlled situations of counterconditioning, response prevention, posture-facilitated subordination, and relaxing massage. Under the structure and control of such training, aggressive impulses may periodically occur, but they are usually inhibited and subside before reaching the critical threshold for attack. Graduated exposure to physical control and restraint helps to improve a dog's ability to control aggressive impulses, while

learning to rely on more constructive and cooperative means to control irritating, frustrating, or threatening situations. As a result, in addition to affectionate affiliation, a growing sense of respect and trust may develop toward the owner, in direct proportion to the owner's success in becoming an effective leader through training.

As a buffer of enhanced affection and impulse control is established, the next step in the process involves developing a playful response. As discussed previously, play provides a powerful means for mediating affiliative connectedness with dogs. Unfortunately, dominant-aggressive dogs are not always very interested in play and may resist efforts to elicit such interaction. Dogs unwilling to play may be encouraged by doing things with them that they enjoy and that may gradually be turned toward more playful interaction. Activities that simply require a dog to follow its owner's lead (e.g., a nature walk) or, perhaps, making a game of fetching or finding a hidden treat can provide a foundation for more spontaneous play as the dog learns to relax. An intensive daily exercise program can also produce striking benefits in some dominance aggressors, especially in cases in which comorbid depression is present—depression may make a dog emotionally vulnerable to increased irritability and aggression.

PLAY AND AGGRESSION

Play offers a powerful nonintrusive means to control the direction of social polarity and attention, to balance affection and leadership, and to increase feelings of affiliation and cooperation between people and dogs. Play is relatively incompatible with aggression and fear, although, under the influence of escalating frustration or threat, play may slip over into overt aggression.

What Is Play?

Among potentially aggressive social animals that establish close affiliative relations with one another, play appears to mediate and consolidate *friendships.* Playful interaction among conspecifics appears to take two general forms: some forms of play promote social affiliation and are done apparently for the joy of playing, whereas other forms of play may be used to probe the strength and character of the playful competitor. In terms of behavior, the general qualities associated with play are behavioral openness, curiosity, and flexibility. Playful activity is characterized by an ostensible purposeless purpose in which action is governed by factors independent of serious intent (Immelmann, 1980). Intraspecific play involves the exchange or expression of various species-typical behavior sequences that are emitted out of normal order and in the absence of natural triggers. Playful behavior is often exaggerated and solicitous, random and incomplete, and, in the case of aggressive components, occurs within a safe range of intensity (escalating and abating) over the course of the play episode. In addition, play often involves explicit and inappropriate sexual behavior (e.g., male dogs mounting other males). A large percentage of a dog's play behavior involves competitive components incorporating low-intensity threats and aggressive displays kept within noninjurious limits. Actually, competitive play is structurally comparable to actions, which, if emitted under the influence of aggressive establishing operations and contexts, could result in severe injury or even death to the players. For dogs, play is an essential element in the development of healthy social attitudes and essential interactive repertoires with other dogs and people (Fagen, 1981).

Metacommunication and Play

Play depends on the exchange of various auditory, facial, and bodily expressions (e.g., play bow and play face) defining an intent to play. These play invitations are highly ritualized patterns of mutual identification, feigned diminutiveness, and neotenic care-seeking and active-submission behaviors. Bateson (1976) characterizes these various preliminary messages as a form of metacommunication, that is, expressive signals forming a communicative context by which the participants can properly interpret the behavioral events that follow. During an invitation to play, these vari-

ous messages are communicated to reassure the other (and perhaps the sender) that the activity is, in fact, just play. According to Bateson, these various signals state, "These actions in which we now engage do not denote what those actions for which they stand would denote [otherwise]. . . . The playful nip denotes the bite, but it does not denote what would be denoted by the bite" (121). In other words, the preliminary signals communicate about the forthcoming events in terms that reach *beyond* the obvious denotations. He argues that the mammalian evolution of play signals may represent an important evolutionary step in the development of communication. Buytendijk (1936) argues that a dog's ability to communicate symbolically through gesture, body language, and vocalization has played a vital role in its successful domestic adaptation:

> Taking one thing with another, there is indeed no other animal in our environment that has so many means at its disposal for rendering the intensity of its actions symbolic. This explains (1) why man has ascribed to the dog as intense a faculty of feeling as he himself possesses; (2) why man believes he understands the dog; (3) why the dog is so exceptionally capable of accompanying man, and of being spoken to and treated as a house-mate, a friend, and brother. (65)

A common example of metacommunication related to play is the play smile or canine grin. Many dogs exhibit a "smile" during greetings and other times of excitement. The grin is superficially similar to the baring of teeth exhibited during agonistic displays. Both the grin and the snarl are formed by retracting the upper lip back and exposing the incisors and canines. Although a grin is sometimes confused with a snarl, many facial and bodily indicators confirm a nonaggressive and prosocial intention. Instead of communicating a threat, the play smile clearly invites playful social interaction. Darwin (1872/1965) long ago gave a very plausible account for the development of this canine social custom:

> Some persons speak of the grin as a smile, but if it had been really a smile, we should see a similar, though more pronounced, movement of the lips and ears, when dogs utter their bark of joy; but this is not the case, although a bark of joy often follows a grin. On the other hand, dogs, when playing with their comrades or masters, almost always pretend to bite each other; and they retract, though not energetically, their lips and ears. Hence I suspect that there is a tendency in some dogs, whenever they feel lively pleasure combined with affection, to act through habit and association on the same muscles, as in playfully biting each other, or their masters' hands. (120)

In another insightful passage, he keenly describes another common example of metacommunication at work:

> When my terrier bites my hand in play, often snarling at the same time, if he bites too hard and I say *gently, gently,* he goes on biting, but answers me by a few wags of the tail, which seems to say "Never mind, it is all fun." (120)

It should be noted that the canine grin may function in a variety of ways, some of which may be ambiguous and not indicative of an intention to play. Some dogs under the influence of conflicted or nervous intentions may grin in an effort to cut off interaction. Cutoff signals appear to be offered as gestures of compromise in situations involving social conflict (see *Cutoff Signals* in Volume 1, Chapter 10). The cutoff or compromise signal is not a submissive gesture but an opportunity for the contestants to call a draw and disengage without loss or gain. Generally, the cutoff signal appears to have a mutually pacifying effect that curtails tensions before they escalate into more serious conflict. Cutoff signals are often presented during playful activity, especially when things get too competitive or threatening for one of the players.

A common form of metacommunication exchanged by playing dogs is the play bow. Bekoff (1977) studied the function of play signals in both domestic and wild canids and observed that the play bow serves two primary functions: (1) the signal communicates an animal's intention to play in the first place, and (2) the signal confirms the continuance of a playful mood, thus preventing play from escalating into more serious fighting. Bekoff observed that play bows occur more frequently after certain agonistic actions (e.g., biting and

side-to-side head shaking) that might be misinterpreted by a playful opponent as a threat (Bekoff, 1995). He argues that play bows under such circumstances may serve to disambiguate the meaning and playful intention of such behavior:

> In addition to sending the message "I want to play" when they are performed at the beginning of play, bows performed in a different context, namely during social play, might also carry the message "I want to play despite what I am going to do or just did—I still want to play" when there might be a problem in the sharing of this information between the interacting animals. (426)

In the case of play between adult dogs and puppies, the former might lie down on its side or back and engage the latter in jaw wrestling and gentle pawing. Figuratively speaking, each player must temporarily discard its social armor and weapons in order to play. Play may evoke a shared sense of relief from the various accustomed expectations and roles ordinarily required from each of the participants. Between familiar dogs, dominant-subordinate roles change fluidly during play, but such transitions may be more stiff and tenuous in the case of unfamiliar dogs playing for the first time. In such cases, there is a significant risk that play may inadvertently escalate into overt fighting. Play may also turn aggressive when one of the participants abruptly decides to quit before the other is ready. Usually, however, play is peaceful and socially constructive, functioning to promote harmonious interaction and mutual tolerance between play partners.

Social Learning and Play

The ability to play is contingent on a balance of health and emotional stability. Overly aggressive, fearful, depressed, or sick dogs do not show significant interest in play. Play exudes a sense of security and well-being together with an open willingness to accept come-what-may during the course of playful interaction and exploration. Play encourages an empathic sensitivity involving gentleness and tolerance while expressing oneself in aggressive and sexual forms. Eibl-Eibesfeldt (1971) reports that animals that fight among themselves as adults practice agonistic skills as young, learning appropriate restraints and bite inhibition. If one partner in play bites too hard, the "injured" play partner yelps, quits playing, and may retaliate in earnest, thus teaching the aggressor better bite inhibition in the future. It is very likely that play is the means by which dogs learn appropriate restraint and inhibition over aggressive and other socially disruptive behavior patterns (Bekoff, 1972). In many respects, play is a socially unifying activity that stands in direct opposition to the socially dispersing influence of agonistic behavior. Bekoff (1974) concluded from a comparative study of coyotes, dogs, and wolves that "canids which play together tend to stay together" (227). He found that the relative amount of play exhibited versus agonistic behavior in early life is a reliable indicator of the degree of sociability exhibited by the animal as an adult. Play appears to serve an important role in the facilitation of long-term affiliative behavior among wolves and dogs—a tendency that is notably lacking in the more socially aggressive and *lonely* coyote.

Among wolf pups, aggressive behavior and biting peak between weeks 8 and 12. During play, participants learn "the fact that hard biting results in *aggressive reaction* (italics added) by the wolf who has been bitten" (Zimen, 1981:186). As the result of aggressive retaliation and submission, play becomes more friendly and social interaction progressively more orderly and peaceful as bite inhibition develops and the puppy learns to benefit from social signals. In combination, social dominance and competitive success over the control of food and other resources facilitate the emergence of more or less stable dominance relations between competing littermates. As a result of such competition, a ranking order is established to promote more peaceful and cooperative interaction and the prevention of disruptive fighting. As the result of playful sparring and aggressive competition, the puppy appears to internalize a lasting impression of its relative status (that is, its general ability to control others in a competitive context). Although highly aggressive puppies may secure and maintain dominance from an early age, the

process of social definition is usually labile, with dominance relations becoming progressively stable between littermates between weeks 11 and 17 (Scott and Fuller, 1965).

Play facilitates social learning between dogs and between people and dogs. The presence of interactive tolerance and the exchange of affection during bouts of play provide an atmosphere of flexibility under which puppies and dogs can readily learn self-control and interactive restraint. This readiness coupled with a playful puppy's ability to switch back and forth quickly from behaviors belonging to unrelated functional systems gives play the ability to facilitate the formation of unique or new linkages, flexibility that is extremely useful for behavioral training efforts and the modification of various behavior problems. Play and exploratory curiosity are essential to learning both about the environment and about others—canine and otherwise:

> The animal collects experiences during play with conspecifics and learns the possible range of its own movements. Play always implies a dialogue with the environment, and this dialogue is always the result of an internal drive. One could even assume a separate drive for play, but I am inclined to believe that the drive to learn, which is the basis of all curiosity behavior coupled with an excess of motoric motivation, will suffice to account for the phenomenon of play. (Eibl-Eibesfeldt, 1970:240)

An important use of playful interaction among animals is the testing and probing of social relations, including social status. Pellis and Pellis (1996) note that the dominance-testing function of play is especially relevant in the case of postpubertal animals:

> We suggest that the primary function of postpubertal play fighting is that of social manipulation, either to recruit or maintain "friendships," or to improve one's status in the group. For the latter purpose, one animal has to test and probe its relationship with another. If such probing reveals weakness, the performer can increase the intensity or roughness of play or even switch to more explicitly agonistic behavior. In this way, the performer may intimidate the opponent, thus gaining access to current or future resources. But what if such rough play meets with strong resistance? The problem is then to back down, or de-escalate the encounter. An amicable signal that conveys the message "it was only play" would be invaluable. (260)

During playful interaction, aggressive behaviors are emitted at very low intensities and dogs are much more tolerant of provocative handling. Further, since dominant-subordinate roles are more fluid during play, a dominant dog or puppy can be more easily encouraged to adopt a subordinate role and learn the benefits of cooperation and submission by making various rewards available at such times. In an important sense, effective behavioral training is play with a structure and purpose. Structured play interaction provides an excellent tool for the modification of many emotionally debilitating problems besides dominance aggression. Play is commonly combined with other behavior-modification procedures in the management and control of fearful behavior, social excesses, and a variety of impulse-control problems.

Note: Initiating play with a dominant-aggressive dog with a history of serious attacks is potentially very dangerous. Such activities are only slowly and carefully introduced after significant behavior modification has taken place to reduce the risk. Dominant-aggressive dogs often exhibit a striking lack of interest in play and may resent playful initiatives and respond aggressively if prompted to play.

Cognition and Aggression

Among highly evolved animals like dogs, executive cortical systems exercise significant regulatory control over the expression of emotional behavior. These cognitive appraisal and regulatory processes serve to excite or inhibit relevant motivational substrates selectively. Cognitive influences finely tune the dog's emotional state and prepare it for action according to the needs defined by the moment-to-moment circumstances confronting it, thus giving behavior a high degree of expressive accuracy and subtlety. Cortical and subcortical interactions are analogous to the relationship between a conductor and an orchestra. Although the orchestra is composed of many disparate musical instruments and sounds, it is given harmonious organization and direction under the executive command

of the conductor's baton, thereby producing music instead of cacophony.

Unfortunately, executive cognitive control efforts often fail to regulate highly motivated behavior such as fear and rage. The afferent and efferent interconnections between the cortex and the subcortical areas responsible for the elaboration of fear, anger, and rage are asymmetrical, with stronger input going into the cortex than leaves it to modulate the activity of these influential areas of the brain (see *Cerebral Cortex* in Volume 1, Chapter 3). In other words, one cannot just command "Don't be afraid" or "Don't be angry" and expect the subcortical areas involved to be quieted. Executive control is not exerted like an on-off switch that activates or deactivates the selected arousal system; instead, such influences are mediated through the cortical activation of opposing motivational systems: *contraries cure contraries.* For example, an angry impulse may be offset by an opposing fearful impulse that is evoked by a *recognition* that aggression will probably not succeed and may actually fail and possibly cause the perpetrator harm. In this case, fear appears to restrain anger, whereas, in other cases, anger may reduce fear.

The central arousal of fear competes with anger and elevates behavioral thresholds for aggressive behavior, but only if such stimulation occurs before an attack is launched. Once an attack is under way, threats and efforts to physically punish aggressive behavior typically worsen the situation. Under the potentiating influence of rage, aggressive efforts become progressively immune to the restraining effects of fear. To inhibit aggression, fear must reach a sufficient threshold to generate an inhibitory response before a dog commits to an aggressive action. Once aggression occurs and rage is elicited, it is too late to attempt to restrain the behavior with fear-eliciting tactics. Finally, it appears that emotional impulses are hierarchically organized, with some being prepotent and inhibitory over the expression of less potent subordinate impulses (Izard, 1993). Although fear and anger tend to exert reciprocal inhibitory effects on each other, the relationship between rage and fear is not reciprocal: rage restrains fear, but fear does not appear to restrain rage.

ANXIETY, FRUSTRATION, AND AGGRESSION

Aggression (threat or attack) is driven by aversive affective states, prompted by natural or learned triggers, and guided by cognitive appraisal. Clearly, an increased likelihood of aggression occurs under conditions of heightened anxious or frustrative arousal (Figure 8.3). Both anxiety and frustration, occurring as the result of loss or threat, may trigger preparatory arousal (vigilance and behavioral invigoration) and lower aggression thresholds (Figure 8.4). Just as anxious arousal appears to reflect a mild stimulation of the fear system, frustrative

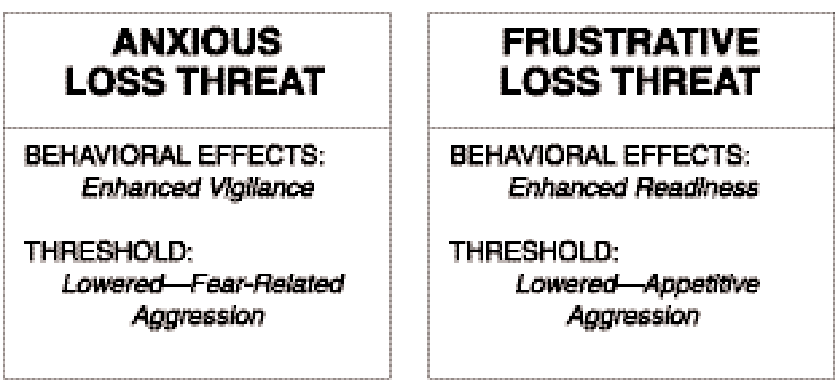

FIG. 8.3. Control-related aggression thresholds are lowered by the presence of anxiety (enhanced vigilance) and frustration (enhanced readiness).

arousal may reflect mild activation of the aggression-rage system (Panksepp, 1998). In addition to the threshold-modulating influences of anxiety and frustration, a dog's disposition to behave aggressively depends on a past history of agonistic successes and failures. For example, under conditions of forceful restraint, both anxiety and frustration may be evoked, triggering autonomic arousal and behavioral invigoration that may result in aggressive efforts to escape. If the aggressive effort is successful, both anxious and frustrative arousal are immediately reduced and replaced by opponent relief and elation, potentially providing significant reinforcement for the behavior. Under similar circumstances in the future, stimuli associated with the situation may elicit preparatory anxious arousal in advance of impending restraint, thereby causing the dog to threaten or attack even before it is touched; that is, the dog may learn to respond preemptively to situations portending loss or threat. The decision to threaten or attack appears to be regulated by a cost-benefit assessment of the situation. Aggression is most likely to occur under circumstances in which the likelihood of success is high and the potential costs are low if aggression fails. Conversely, aggression is least likely to occur under circumstances in which the likelihood of success is low, and where a significant cost is at risk if aggression fails. Aggressive behavior is most likely to conform to a cost-benefit analysis under social circumstances that are both highly predictable and controllable. However, under the influence of uncontrollable and unpredictable circumstances involving high levels of anxiety and frustration, aggression may occur in a much more erratic and impulsive way (Figure 8.5).

To a significant extent, the behavioral treatment of aggression problems involves altering behavioral thresholds by appropriately modifying anxiety and frustration levels. Conditioned anxiety is addressed by means of various classical conditioning procedures, whereas conditioned frustration is modified by instrumental training efforts that give dogs constructive alternatives with which to control or cope with frustrating or threatening situations. In combination, these various behavior-modification procedures help to systematically disconfirm anxious-frustrative expectancies mediating aggressive behavior by fostering incompatible expectancies based on security and confidence, that is, heightened trust. Systematic training activities provide dogs with a highly predictable and controllable framework for experiencing and coping with motivational adversity.

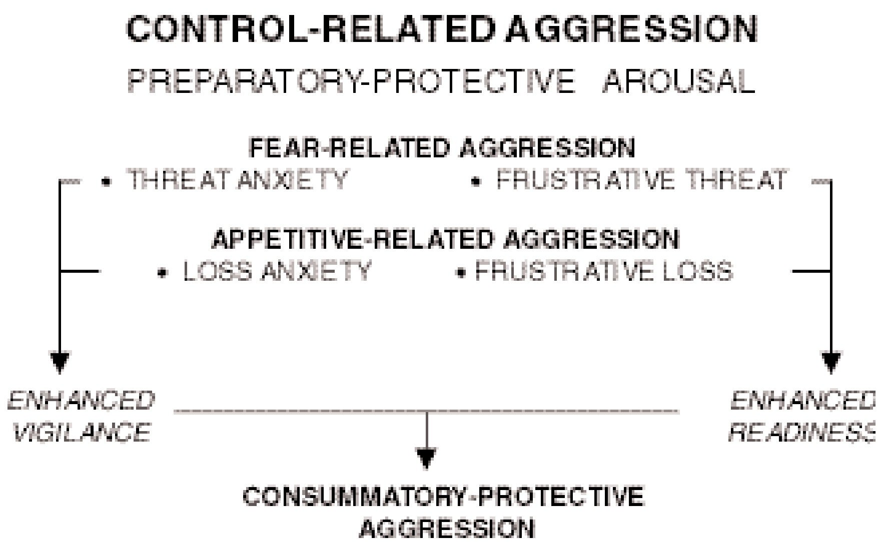

FIG. 8.4. Anxiety and frustration serve to prepare dogs for aggression by enhancing vigilance and motivational readiness.

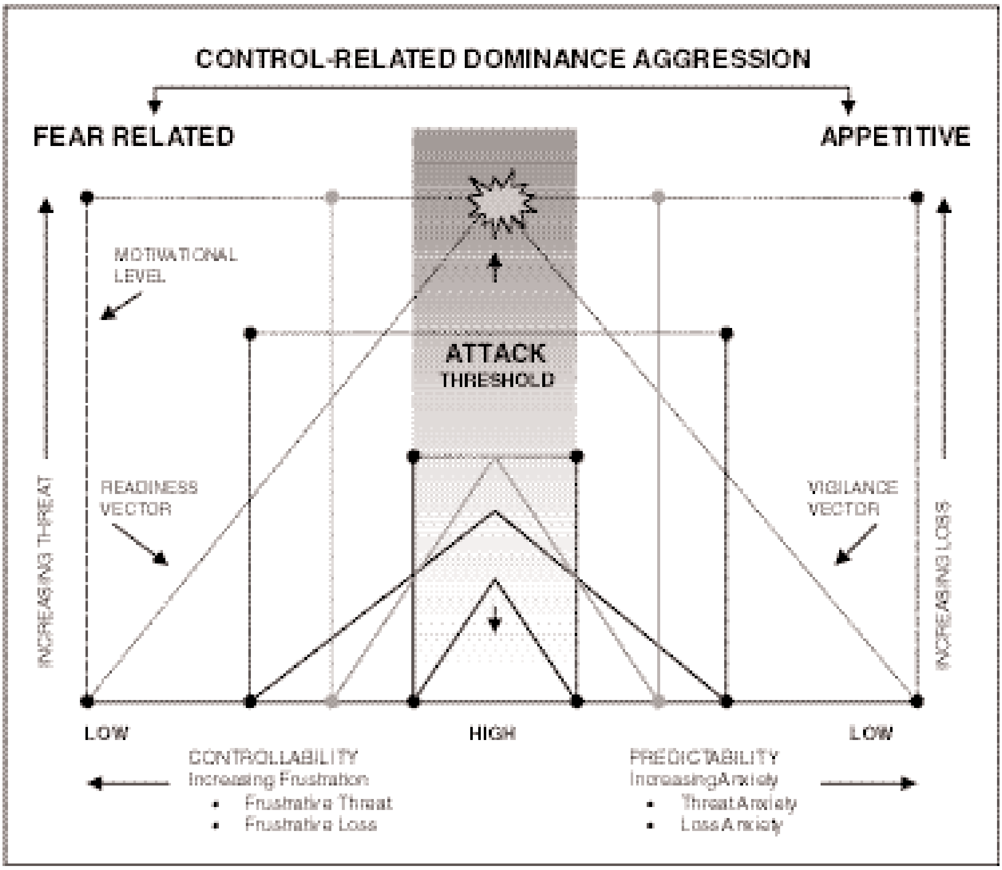

FIG. 8.5. Various contributory cognitive and motivational factors interact to influence the attack threshold. The perceived controllability and predictability of the situation exercise a pronounced influence. Under enhanced motivational conditions of impending threat or loss, vigilance and readiness vectors angle steeply in relation to the degree of control or predictability present, with an attack most likely under conditions where the event is both unpredictable and uncontrollable. Note that the likelihood of attack is correspondingly reduced as the size of the threat or loss is reduced and the event's controllability/predictability is increased.

BEHAVIORAL THRESHOLDS AND AGGRESSION

The vast majority of dogs go through life without ever exhibiting dominance-related aggression problems. Many dogs are exposed to similar rearing and training practices, but relatively few of them develop serious aggression problems. Presumably, permissive and unassertive owners would be more likely to foster dogs exhibiting dominance-related problems. Although some putative differences between owners of aggressors and nonaggressors have been suggested from time to time, nothing robust or explanatory has been identified. In fact, most studies to date have found little or no correlation between owner personality traits, anthropomorphic attitudes, or spoiling activities and the incidence of dominance-related aggression problems (Dodman, 1996; Goodloe and Borchelt, 1998; Voith et al., 1992) The relative independence of aggressive behavior and owner rearing or training practices reduces the likelihood that dominance-related aggression problems are caused primarily by status conflicts.

The control theory of aggression escapes similar criticism by emphasizing motivational considerations, such as anger, frustration, and

irritability. These aggression-promoting establishing operations are offset or modulated by incompatible or affiliative establishing operations, such as affection and trust. The essential difference between control- and status-related dominance aggression is that control-related aggression is emitted in order to dominate some situation without reference to the relative status of aggressor and victim, whereas status-related aggression is emitted under circumstances in which a subordinate (past loser) fails to recognize and appropriately defer to an opponent's dominant status. Although status may be a significant factor in some cases of interspecific dominance aggression, unless the *status* concept is carefully delimited in functional terms, it may only confuse matters and impede training efforts. The status of social competitors is an emergent attribute defined by their relative successes or failures resulting from past conflicts and contests: winners are dominate and losers are subordinate. A potentially useful way to understand status in functional terms is provided by the control-vector analysis discussed in Chapter 7. In essence, status signals power and a history of aggressive success.

Many biological factors disposing dogs toward competitive success are inherited, for example, its size and physical health. In addition, various behavioral thresholds conducive to combative success appear to be inherited. Price (1998) argues that the primary effect of domestication on behavior has been to alter behavioral thresholds. Of particular interest is the alteration of behavioral thresholds controlling the freeze (mild fear), flight (strong fear), and fight reactions. Obviously, not all dogs show the same response to aversive stimulation; these differences of behavior are primarily due to emotional and behavioral thresholds. For example, some dogs exhibit a very low fear threshold and may freeze or flee in response to minimal fearful stimulation [e.g., fearful pointers (see *Nervous Pointer Dogs* in Volume 1, Chapter 5)], whereas other dogs may exhibit a very high fear threshold and exhibit extraordinary tolerance for such stimulation (Krushinskii, 1960). On the other hand, some dogs exhibit a low aggression threshold to provocative stimulation and are quick to *fight* in response to minimal annoyance, whereas other dogs, possessing a high aggression threshold, may become aggressive only under the most extreme and provocative stimulation. Combining these opposing behavioral thresholds results in four sets of characteristics, latencies, and predictions (Figure 8.6). During competitive contests, dogs combining a low aggression threshold and a high fear threshold (quadrant 2) enjoy an advantage over opponents exhibiting a high aggression threshold and a low fear threshold (quadrant 3). For example, a dog that attacks with minimal provocation is likely to dominate a more inhibited counterpart who submits or runs away when minimally threatened (Pawlowski and Scott, 1956). Also, the tendency of male puppies to dominate female puppies may be due to the threshold-lowering effects of perinatal androgenization on neural substrates mediating the expression of aggressive behavior. Although these various thresholds are significantly influenced by biological factors, they are also subject to the actualizing influence of experience and learning (Krushinskii, 1960). Typically, dogs exhibiting control-related dominance aggression problems fall into quadrants 1 and 2. An important aspect of treating such problems involves systematically altering behavioral thresholds in the direction of quadrant 4. In the case of dogs exhibiting characteristics belonging to quadrant 1, behavior-modification efforts should aim at simultaneously elevating aggression and fear thresholds, whereas, in the case of dogs showing characteristics belonging to quadrant 2, training efforts should be primarily focused on elevating the aggression threshold. Note that attempting to increase control by lowering fear thresholds (flight) in dogs belonging to quadrant 2 may inadvertently push them in the direction of quadrant 1, with an increased risk of aggression and rage—an unfortunate and common iatrogenic outcome of training in cases in which overt aggression is physically punished.

This general scheme nicely explains how a dog possessing a high aggression threshold and a low fear threshold (quadrant 3) might be induced to attack. Under circumstances in which such dogs are strongly aroused with fear but prevented from escaping, the fight threshold may be finally reached, causing the

	LOW-FLIGHT	HIGH-FLIGHT
LOW-FIGHT	1 LOW-FIGHT/LOW-FLIGHT *LATENCY:* Quick to aggression- Quick to fear *PREDICTION:* High probability to exhibit aggression with significant rage potential	2 LOW-FIGHT/HIGH-FLIGHT *LATENCY:* Quick to aggression- Slow to fear *PREDICTION:* High probability to exhibit control-related dominance aggression
HIGH-FIGHT	3 HIGH-FIGHT/LOW-FLIGHT *LATENCY:* Slow to aggression- Quick to fear *PREDICTION:* High probability to flee--low probability of aggression, unless flight is blocked	4 HIGH-FIGHT/HIGH-FLIGHT *LATENCY:* Slow to aggression- Slow to fear *PREDICTION:* Low probability for aggression or fleeing, except under the most extreme duress or threat

FIG. 8.6. Matrix of behavioral thresholds controlling flight (fear) and fight (aggression).

dogs to attack the source of stimulation. If the attack is successful, such dogs may form a highly undesirable inference about how to control fearful stimulation or threats in the future, thereby lowering the controlling threshold for aggression. When threatened in future, a quadrant-3 dog may threaten or attack preemptively instead of waiting and possibly being hurt again. This *learned trigger* overrides or bypasses low-threshold fear inhibitions (freeze or flee) and directs the dog to attack. In this case, the dog attacks—not because of fear but in spite of fear. Under such influences, aggressive behavior may be liberated from modulatory threshold influences and natural triggers, gradually being elicited by a variety of stimuli and in minimally provocative and inappropriate contexts.

Under the assault of aversive stimulation, escape appears to be prepotent over attack, but attack is easily learned as an escape/avoidance response if it serves to terminate aversive stimulation (Azrin et al., 1967). The inhibitory effects of fear are especially compromised in situations where aggression has proven more successful than submitting or running away in the past. This particular form of aggression is especially responsive to behavior modification, since the *learned trigger* can be counterconditioned, causing the aggression threshold to gravitate gradually back to its *natural* level. In addition, such dogs are often very inhibited aggressors that seem to want to find a way out of conflict situations without resorting to aggression.

Theoretically, puppies exhibiting quadrant-1 traits would be at a higher risk of developing aggression problems as adults, regardless of owner rearing and training practices. When exposed to aversive stimulation, such puppies may respond to the punishing agent (e.g., the owner) with both fear and anger—a highly undesirable state of affairs. As a result of such motivational collision, fear may become progressively linked with anger and aggression. Instead of inhibiting attack (submission) or causing such puppies to submit, the elicitation of fear may stimulate aggression through its linkage with anger and rage circuits. Punishment in such cases may only stimulate more anger and aggression. The result is a spiraling escalation of rage, continuing until aversive stimulation is stopped. Conceivably, if such motivational cross-linkages are formed early enough in a dog's development, especially before fear and anger/rage neural circuits are fully differentiated and segregated, a very serious and explosive form of aggression might be incubated and finally expressed in adulthood (Panksepp, 1998).

Aversive Trauma, Social Loss, and Aggression

Although abusive treatment should be avoided in the rearing of dogs, punishment per se (even when highly aversive and noncontingent) may not always result in a predisposition for aggression or fearfulness in puppies with sufficiently high behavioral thresholds for aggression and fear. Although a history of abuse and trauma may represent a necessary cause, these experiences alone are not sufficient for the development of adult social behavior problems involving excessive fear or aggression. In fact, as shown by Fisher (1955), many puppies appear to be surprisingly resilient to the effects of traumatic treatment (see *Early Trauma and the Development of Behavior Problems* in Chapter 4). Fisher's findings draw into question the role of adverse and traumatic conditions in the development of maladaptive behavior in dogs. The modulating effects of behavioral thresholds provide a key to understanding why some dogs can undergo detrimental experiences but not exhibit lasting signs of disturbance, whereas others appear to be profoundly and permanently debilitated by such experiences. Pavlov (1927/1960) was the first to recognize that certain temperament types are more susceptible to the elaboration of neurotic disturbances; especially vulnerable are those dogs prone to excessive excitation (choleric) or inhibition (melancholic) (see *Experimental Neurosis* in Volume 1, Chapter 9). Detrimental environmental conditions are most likely to exert lasting disturbances in dogs possessing excessively low thresholds to aversive stimulation. According to this analysis, a genetic predisposition affords conditions under which exposure to traumatic events may provide the conditions (distal setting events) under which influence adversity (proximal establishing operations) may result in persistent aggressive or fearful behavioral disturbances. Normally, aggression is physiologically and psychologically self-limiting and used only under adverse motivational conditions (e.g., frustration, irritability, and threat). Aggression occurring outside of this basic pattern is often the result of neurotic elaborations or an underlying physiological pathology.

Depending on individual temperament variations, stressful separation and loss may exert a pronounced effect on a dog's behavior by increasing social avoidance and aggression—changes that may persist even after contact with the attachment object is restored. E. C. Senay (1966) studied behavioral changes occurring in dogs following an abrupt cessation of social contact (abandonment) and subsequent reunion after 2 months of separation. Beginning at week 3 and continuing until 9½ months of age, the researcher established close contact with six German shepherd littermates. The behavior of the puppies was carefully monitored and evaluated prior to separation, after separation, and after reunion. During the 2-month period of separation (from 9½ to 11½ months), a noninteractive caretaker cleaned their pens and fed them.

From the onset and over the course of the study, the puppies exhibited consistent behavioral tendencies in terms of social affiliation and approach scores versus avoidance and aggression scores. Three of the puppies were highly cooperative and socially attracted to

the experimenter and actively sought to maintain close contact with him (*approach temperament*), whereas the other three exhibited varying degrees of avoidance and aggression (*avoidance temperament*). Puppies exhibiting affiliative-approach tendencies received the highest scores with respect to responsiveness to discipline and trainability. These puppies showed a minimum amount of social avoidance when disciplined and a high degree of responsiveness to training. In contrast, socially avoidant and aggressive puppies received the lowest discipline and trainability scores, exhibiting a high degree of avoidance and resistance to training efforts.

Puppies exhibiting the highest preseparation approach scores showed increased social interest and attraction toward rater-observers entering the holding pen during the period. On the other hand, puppies exhibiting high avoidance and aggression scores prior to separation became even more avoidant and aggressive during the 2-month separation period. Interestingly, puppies with *avoidance temperaments* showed a significant decrease of activity during the separation period. Upon reunion with the experimenter, the trends toward increased attraction and affiliation, on the one hand, and increased avoidance and aggression, on the other, continued to increase during the first 2 weeks after reunion, before returning to preseparation levels after another 2 weeks of restored contact with the experimenter.

Senay observed a strong correlation between arousal levels and temperament type. Avoidant-aggressive puppies tended to exhibit a high level of general arousal and excitability, with tachycardia and excitable urination being exhibited by the most avoidant and aggressive puppies in the group, whereas puppies exhibiting less excitability and reduced arousal levels showed more approach behavior and *no* aggression:

> Early in life the animals seemed to possess differences in their neurophysiologic arousal systems. These differences seemed to determine whether object presentation [presence of the experimenter] would have organizing (approach temperament) or disorganizing (avoidance temperament) effects on the behavioral patterns of the animals. . .. The observations made here suggest that with stimulation from the object held constant, animals possess individual differences in their arousal mechanisms and furthermore, that these differences are crucially involved in separation phenomenon. (70–71)

These findings underscore the importance of affectionate affiliation for the control and prevention of aggression problems, and emphasize the role of behavioral thresholds in their etiology and development. Separation from an attachment object may produce significant stress and alter avoidance and aggression thresholds in predisposed dogs possessing an *avoidance temperament,* while enhancing affiliative bonding and cooperation in dogs influenced by an *approach temperament.* Interpreted from a behavioral perspective, separation represents a setting event (distal influence) that motivationally alters a puppy's later responsiveness to establishing operations (proximal influence) associated with avoidance and aggression. Early traumatic experiences can be interpreted in similar ways. Predisposed puppies exposed to an excessively frightening experience (setting event) may be more responsive to similar conditioned and unconditioned experiences (establishing operations) occurring later in life. The early traumatic setting event may consequently cause such dogs to acquire related avoidance or aggressive behavior more rapidly and efficiently.

LEARNING AND DOMINANCE

As has already been repeatedly emphasized, dominance is synonymous with control. Dominance contests occur when a dog is prompted to do something it would prefer not to do, constrained to forego some preferred activity, or required to relinquish some possession it would prefer to keep. Consider, for example, a competitive contest by two dogs over a location or resource (Figure 8.7). During the contest, the more dominant of the two opponents will *prompt* the subordinate with a direct threat (e.g., stiff posture, stare, and snarl) to withdraw from the situation. If the subordinate fails to defer, the dominant animal may escalate its threats, or attack if its threats continue to be ignored. Assuming that the dominant dog's efforts are

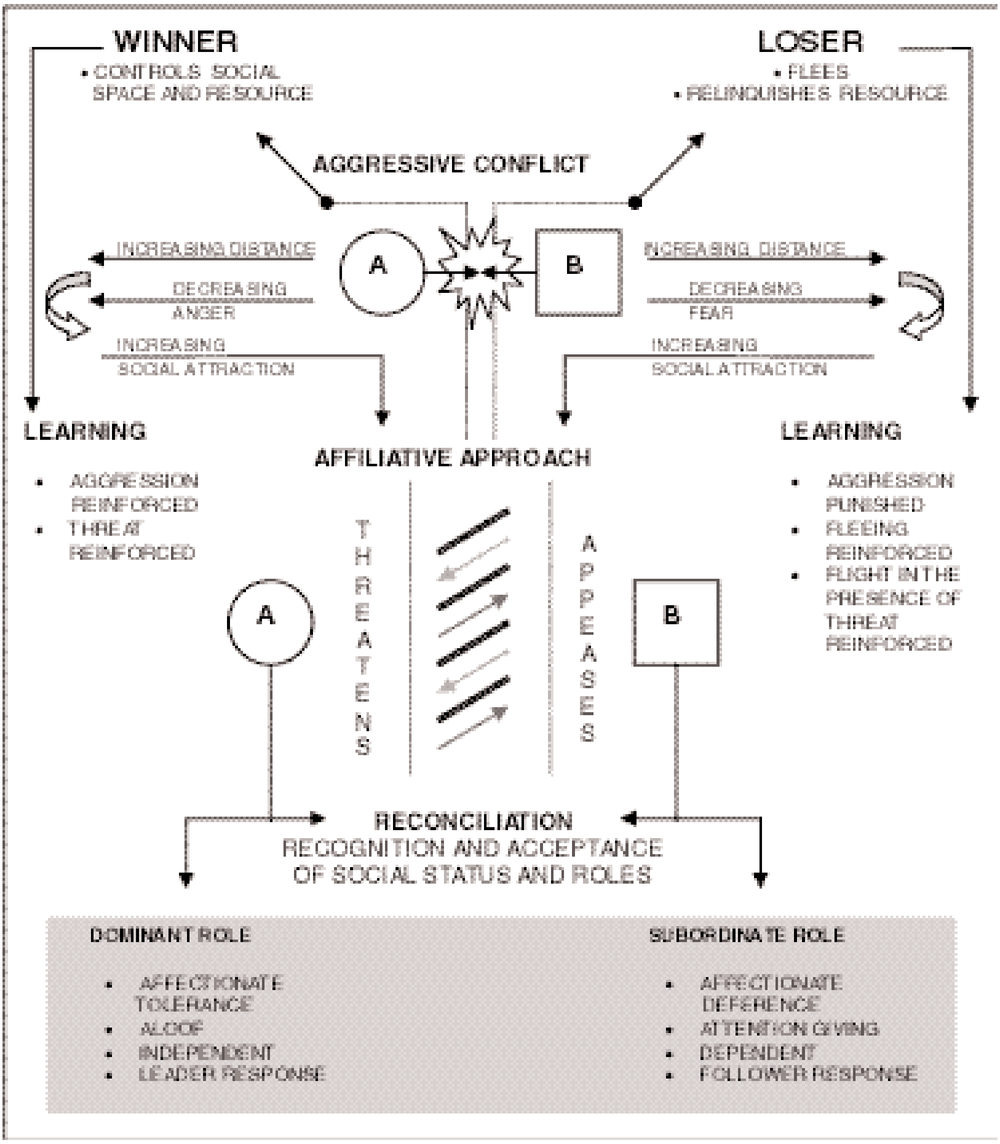

FIG. 8.7. Various outcomes resulting from agonistic interaction. Immediately following an aggressive encounter, anger and fear enhance social distance between combatants. Over time, anger and fear wane and are replaced by increasing levels of social attraction and affiliative interest. As contact is restored, threat and appeasement displays facilitate reconciliation, with opponents recognizing each other's social status and respective roles. Note the various effects that learning has on aggressive interaction.

successful, both the assertive behavior of the winner and the flight/submission of the loser are reinforced, but the reinforcement experienced by the two contestants is based on opposite reinforcing effects. The dominant dog's assertive behavior is positively reinforced twofold, since it successfully displaced the rival, as well as served to secure the resource (e.g., a bone). The subordinate's behavior is both punished and negatively

reinforced. On the one hand, the subordinate's competitive adventure failed to control the resource (punishment), whereas, on the other, it succeeded in escaping the dominant dog's attack. As a result, during future competitive interaction between the two dogs, the dominant animal will be more likely to successfully assert rank, whereas the subordinate will be more likely to submit or flee. In addition, the subordinate will likely learn to avoid future contests with the winner. By exhibiting submissive behavior toward the threatening rival, the subordinate avoids attack and its submissive behavior is reinforced. Likewise, the subordinate's deferential response to threat or attack reinforces such displays in the dominant dog. In the future, contests between the two rivals are resolved largely through the exchange of ritualized threat and appeasement behaviors—displays that are highly *prepared* (species typical) and quickly learned.

Threat and appeasement displays may be conceptualized as triggers producing opposite establishing operations in the competitors. In the case of dominant animals, appeasement signals evoke motivational changes conducive to reducing aggressive behavior (reduces anger), whereas, in the case of subordinates, threats evoke motivation changes conducive to the emission of submissive behavior and withdrawal (increases fear). In both cases, under the influence of relevant establishing operations and motivational states, corresponding dominant-role and submissive-role *playing* is reinforced.

Following an assertion of dominance, the subordinate may run to a safe distance from the dominant alpha, but, as time wears on, affiliative pressures for social contact will cause it to gravitate back into closer proximity with the alpha. With contact restored, its social separation distress is reduced, thereby reinforcing affiliative behavior and increasing affection for the *magnanimous* alpha. Although the alpha may experience feelings of social loss as well, its distress may be felt much less keenly, since it is compensated with the elation and spoils of victory. Further, the alpha may view the social distance set between itself and its rival as part of its overall success. Dominant dogs possess a certain comfort with social distance, not appearing to need the reassuring social contact sought by submissive subordinates or at least not needing it in the same way or degree. Dominant dogs are more likely to receive affection rather than to give it out.

The direction of affectionate exchange supports the development of dominance-enhancing social polarity between the competitors, making the subordinate less likely to attack the alpha and making the alpha more tolerant of the subordinate's presence. Social polarity is a strong inhibitory and stabilizing influence on the dominant-subordinate relationship. Along similar lines, the alpha is more likely to emit distance-increasing (dispersal) behavior, whereas the subordinate is more inclined to emit distance-reducing (attraction) behavior. If the subordinate is to remain in close contact, however, it must accept a submissive role relative to the alpha's dominant status and prerogatives. Submission-enhancing interaction occurs among all group members until a hierarchy (not necessarily linear) of dominant-subordinate relations and dominance-supporting allegiances is formed.

Following a successful contest, future competitive interaction between the victor and the loser will probably take the form of threat and appeasement displays, indicating the importance of avoidance learning to the process of establishing social dominance. The threat or mere glance alone is now sufficient to evoke submission without needing to resort to an attack, although an occasional aggressive assertion of control may still occur from time to time. This appears to be a desirable arrangement for both the alpha and the subordinate. A possible factor restraining the alpha's use of overt aggression is that such behavior may be intrinsically aversive for it to perform—reminiscent of the reluctance of many owners to punish unruly dogs. Aggression may be *reinforced* insofar as it secures control but is probably not *reinforcing* for its own sake, at least not under normal circumstances. In fact, brain studies involving microstimulation of limbic system areas dedicated to the expression of aggression have

shown that affective aggression is physiologically aversive for the stimulated animal (Adams and Flynn, 1966). Consequently, the alpha is not likely to attack subordinates casually or as a way to obtain *pleasure* at the subordinate's expense. For the subordinate, aggression is doubly aversive, because its own aggressive efforts are both intrinsically aversive and unsuccessful; that is, they result in punishment. Finally, there is always some risk of injury to the alpha as the result of fighting, so avoiding unnecessary combative contests would make sense on the level of self-preservation and safety, as well. Ultimately, the exchange of threat and appeasement display establishes a foundation for social organization and purposeful coordinated activity.

Submission behaviors appear to consist of exaggerated species-typical canine infant behaviors. Among many mammalian species, a strong inhibition prevents adults from attacking their young. Submission displays appear to take advantage of these innate inhibitions and taboos. Such displays are highly prepared responses learned without much experience and triggered by an alpha's threats. In turn, these submissive or appeasement gestures and postures trigger inhibitory control over the alpha's aggressive threats, preventing them from escalating into a full-fledged attack. In the presence of the alpha leader, the subordinate appears to act somewhat like an obsequious infant. These caricature infantlike behaviors appear to evoke paternal (or maternal) caregiving and protective responses toward the subordinate.

Although the subordinate may initially flee and stay away from the dominant victor, in time a growing need for social contact asserts itself. Submissive behavior emerges under the combined influence of fear and social attraction. In an important sense, social attraction overshadows fear and restrains the impulse to flee too far or stay away too long. Much like a rubber band stretched between the alpha and the subordinate, social attraction grows as a motivational tension in proportion to the distance and time spent fleeing. Gradually, needs for social contact attract the subordinate back into closer proximity with the alpha. The subordinate's approach takes place against a building fear gradient but is facilitated under the counterconditioning influence of *affection.* The combination of fear and affection evokes the expression of submissive behavior. In short, *submission* is a motivational composite of *fear and affection.*

Gradually, the subordinate may learn that submissive displays *work* and can be used to manipulate the alpha. This *knowledge is power,* and the clever subordinate may even mock or tease the alpha, thereby narrowing the social distance and disturbing social stability between the two potential rivals. In addition, social polarity is shifted by the amount of attention and effort that the alpha must divert in the direction of the enterprising subordinate. The subordinate may also learn that the alpha does not really like being aggressive. At this point, the subordinate may become overtly obnoxious at times but immediately present a submissive token, if necessary, to placate the aroused and irritated superior. This transition involves a great deal of dominance testing, attention-seeking behavior (active submission), and playful competitive excesses. The alpha may rebuff these excesses but be gradually worn down by the subordinate's relentless and shrewd efforts. As time goes on, a critical point may be reached (especially in socially mature animals) where the provocative subordinate may lose its fear and respect for the alpha altogether and step over the line. If the alpha neglects to act decisively to the challenge, the subordinate may simply take over without a fight. Most often, however, such behavior is met with an immediate and assertive rejoinder, thereby subordinating the challenger (at least for a while). Unless resolved, the two rivals may eventually engage in earnest combat until one is injured, killed, or expelled from the group. These sorts of damaging dominance fights are relatively uncommon in nature but do occur. Serious dominance fights may play a genetic and ecological role in forcing the dispersion of *fit* second-ranking males and females into contact with other similarly expelled counterparts needing mates of their own, thereby encouraging outbreeding and avoiding the dangers of excessive inbreeding between close relatives.

Social Competition, Development, and Aggression

Serious dog aggression problems occur infrequently before the end of the first year and rarely in young puppies. Scott and Fuller (1965) *never* observed any serious attacks or threats in puppies toward humans administering handling tests designed to measure aggressive behavior. Most puppy agonistic behavior is playful, consisting of pawing and inhibited biting actions on hands and clothing. They concluded that "playful aggressiveness and serious aggressiveness are not necessarily correlated" (1965:137)—a finding recently reiterated by Goodloe and Borchelt (1998). Krushinskii (1960), however, has noted research suggesting that some forms of reflexive overt aggression *do* occur in young puppies. In one study, for example, researchers found that a 19-day-old puppy may exhibit an intense aggressive response to being suddenly awakened—a finding that may have relevance for understanding the etiology of this form of aggression in some adult dogs. Although reflexive aggression may be present at an early age, Krushinkii emphasized that "real" aggression toward humans infrequently occurred and not before the end of week 12. Although relatively uncommon, puppies do occasionally present inchoate aggressive tendencies and oppositional behavior that may portend more serious problems in adulthood. It is of great importance, therefore, to identify puppies at risk and to provide them with appropriate socialization and training.

Early Social Learning and Oppositional Behavior

As the result of genetic predisposition and early social learning involving competition with littermates and the mother, a puppy comes into the home *prepared* to accept an affectionate and cooperative (subordinate) place in the family structure, or may bring an enhanced readiness to resist control and assert a real challenge to the family's patience and training abilities. The cooperative and oppositional tendencies of most puppies fall somewhere in between these two extremes. In general, a subordinate or cooperative puppy more readily accepts social control, actively defers when challenged to submit, and exhibits strong bite inhibition, whereas a dominant or oppositional puppy is more likely to defy social control and, when challenged, may resort to aggression, perhaps neglecting to exercise appropriate bite inhibition. Such dominant or oppositional puppies may threaten or snap at family members who attempt to control them, especially around highly motivating activities and resources. The process of establishing control over oppositional puppies can be extremely frustrating and worrisome for novice puppy owners, who may not fully appreciate the potential resistance and persistence of such puppies. This situation is compounded by the owner's sincere desire to affectionately invite the puppy into the home as an equal family member. Unfortunately, affectionate efforts may only lead to unwanted aggressive play and disinhibited mouthing with sharp teeth.

Until the oppositional puppy learns to accept the owner's control and leadership initiatives, it is incapable of forming an affectionate and cooperative relationship. Oppositional puppies may resist instructional efforts to establish household manners, show an unwillingness to accept routine handling and petting, or exhibit intolerance for minimal frustration. In advance of an established leader-follower bond, the oppositional puppy may misinterpret the owner's affectionate efforts, thereby stimulating more social tension and conflict. Finally, early successes involving threats and biting directed against an ineffectual owner may set the precedence for similar behavior in the adult dog. Although it is difficult to make specific predictive statements about the influence of early experience on adult behavior, in comparison to more submissive and cooperative counterparts, puppies exhibiting intolerance for control are likely to continue exhibiting oppositional or aggressive behavior into adulthood unless the problem is addressed with appropriate training. Excessive competition between an oppositional puppy and family members may produce a number of adverse effects:

1. Social aggressive tensions and increased frustration may develop as the result of ineffectual owner efforts to assert control over the puppy.
2. The puppy's perception of social rank may be adversely affected by successfully evading owner control efforts.
3. Evasive chase-and-catch competition over *stolen* objects may be particularly problematical and conducive for the development of aggressive tensions.
4. Abusive punishment occurring out of anger may facilitate the development of defensive aggression.

Although such problems should be addressed and resolved through training, the excessive use of interactive physical punishment should be avoided in favor of positive reinforcement techniques, response prevention, response substitution-redirection, and time-out procedures.

Social versus Competitive (Possessive) Aggression

Competition is a normal aspect of canine social development (see *Social Dominance* in Volume 1, Chapter 2). Competitive success has often been evaluated in terms of a puppy's ability to secure and defend an attractive resource. For example, a common experimental procedure involves giving two hungry puppies a bone or a bowl of food big enough for only one of them to eat at a time. Under such circumstances, one of the puppies will likely displace the other by displaying various aggressive threats or by launching an actual attack, if necessary, to secure control of the bone or food bowl. Under similar circumstances in the future, the loser will tend to exhibit a more deferential pattern of social behavior toward the winner. The value of this procedure for assessing social dominance has been questioned, and some authors (see *Assessment and Identification*) have suggested that social dominance and competitive aggression may actually develop independently and segregate in adult dogs; that is, the dominance aggressor may exhibit competitive (possessive) aggression, but the possessive aggressor is not necessarily dominant and may, in fact, be subordinate in all other situations (Borchelt, 1983). Wright (1980) performed a study designed to evaluate the relation between development, exploratory behavior, social dominance, and competitive (possessive) dominance. In his study, a group of five puppies were tested at three different ages (5½, 8½, and 11½ weeks). The German shepherd puppies showed considerable individual and developmental variations with respect to the expression of social and competitive aggression. Of particular interest was the behavior of the most socially dominant and controlling puppy [no. 2 (male)] when placed into an unfamiliar situation with a littermate and bone. Although otherwise highly aggressive toward littermates, when tested for its ability to control a bone in the novel environment, it scored much lower than less socially aggressive counterparts [e.g., no. 4 (male) and no. 5 (female)], at least during testing done at weeks 5½ and 8½. The two puppies that were most successful in controlling the bone (puppies 4 and 5) in the novel situation were more submissive than puppy 2 when interacting with littermates in familiar surroundings, at least initially. By 11½ weeks of age, however, puppy 2 had become significantly more successful in controlling the bone in the pen situation, superseding the competitive scores of puppy 5 and closing in on puppy 4. Interestingly, puppy 2 also exhibited significant changes in stimulus reactivity and exploration scores at 11½ weeks of age, suggesting the possibility that the puppy's increased competitive success may have been due to a reduction of fear in the novel situation.

The foregoing study does not necessarily support the notion that social dominance and competitive aggression function independently of each other (Reisner (1997). This view represents only one possible way to interpret Wright's findings, but not, perhaps, the most likely one, as Wright points out:

> The relationship between stimulus reactivity and competitive dominance indicates that those puppies that were the least neophobic were also the ones that were best able to control a desirable object in a competitive situation. . . . In other words, the most exploratory and less

> timid puppies were not penalized during the bone-in-pen test by the strange setting, and thus were perhaps better able to control the bone than their more fearful, less exploratory littermates. (1980:23)

The lack of competitive effort exhibited by puppy 2 in the novel setting probably reflects a more general adverse motivational influence rather than the expression of different forms of aggressive behavior. In particular, fear and anxiety (neophobia) associated with the novel setting may be assumed to exert a dampening effect on both appetitive arousal and exploratory activity. In addition, since fear is motivationally antagonistic with aggression, the combined motivational influences associated with the novel setting may have simply suppressed interest in competing over the bone. With regard to the possibility of two forms of dominance (social versus competitive), the study provides no data with which to decide the matter, since appropriate controls were not present to isolate and track such agonistic differentiation independently of the suppressive effects of fear. Fear (neophobia) may generally diminish a puppy's motivation to compete and, in fact, dogs are often more competitive under the influence of familiar surroundings. If puppies had been tested with a bone placed into the home pen, perhaps the apparent differentiation of social dominance and possessive aggression would not have been observed at all. In summary, puppy 2's failure to control the bone in the novel setting at an earlier age may have been due to the inhibitory environmental effects of neophobia over appetitive and aggressive arousal, rather than the expression of different forms of aggressive behavior. Puppy 2's belated success in controlling the bone appears to have been the combined result of maturation and the repeated exposure (habituation) to the novel setting, thus causing a gradual diminution of fear and the simultaneous enhancement of appetitive and aggressive motivation to control the bone.

Temperament Tests and Aggression

Dominant-subordinate relations are formed under the constraints of genetics, maturation, and learning, with competitive relations and incentives changing as a puppy matures. Clearly, the playful competitive sparring between littermates is something quite different from the aggressive contests exhibited by socially mature dogs and wolves. Among adult dogs, for example, competition between adult conspecific males may occur over the possession of an estrus female, something that does not occur among puppies. Although a few constant themes or *individual differences* can be traced out over the course of social development (MacDonald, 1983), the meaning and purpose of competition undergo significant elaboration as an animal matures. The nature of these changes of intention and purpose are defined by biological and social demands placed upon the animal by the interaction of genes, ontogenesis, and environmental pressures. From puppyhood to old age, the direction of these changes is guided by epigenetic processes, incorporating and integrating the aforementioned factors under the selective influence of learning. Developmentally, agonistic behavioral thresholds and corresponding species-typical behavior patterns are strongly influenced by the variable and coordinated expression of genes. The expression of genes appropriate for adaptive success changes as the animal matures. In other words, behavioral traits and abilities appear and become functional according to a genetically orchestrated timetable. The functional influence of genes expressed during the early socialization period is not the same as those influences operating and affecting behavior at puberty or at social maturity. Even cognitive abilities such as *object permanence* are not fully functional in dogs until 11 months of age (Gagnon and Dore, 1994). Genes give structure and order to developmental processes via structural proteins and functional enzymes—enzymes that catalyze biochemical reactions. Enzymes both initiate and regulate the rate of biological activity in every bodily system, including the nervous system, where a precise system of pathways exists between genes, brain structure, neurochemical activity, and behavior (Dewsbury, 1978).

Although an element of continuity certainly exists from conception to senescence, functional elaborations take place throughout the course of a dog's life. These biological

considerations present tremendous challenges for predicting adult behavior based on behavioral tendencies present at earlier stages of development. Over the course of development, genes are variably turned on and off or up- and downregulated under the influence of genes specialized for such purposes. These changes occur in a coordinated manner during a puppy's development. These genetic and experiential influences have important implications for puppy temperament tests and training activities. During early puppyhood, the infant dog's brain and body undergo rapid structural and functional change, reflecting underlying genetic changes controlled by operator genes (turning on or off genes) and regulator genes (increasing or decreasing the activity of genes). Not surprisingly, behavior also undergoes rapid change, and earlier stages of development may not be accurately reflected in later stages of development (see *Temperament Testing* in Volume 1, Chapter 5).

The labile character of aggressive behavior in young puppies makes it difficult to extract any hard and fast predictions about later behavior based on early agonistic indicators. For example, employing a social temperament test believed to perform such a predictive function by some breeders and trainers (Campbell, 1972), Beaudet and associates (1994) were unable to detect a predictive continuity with respect to dominance behavior in young dogs when tested at week 7 and again at week 16. The study involving 39 puppies found that dominance scores at week 7 were not predictive of dominance scores at week 16. The authors conclude that Campbell's test has "no predictive value regarding future social tendencies. In fact, the total value of the behavioral scores for social tendencies between the two age groups showed a trend toward regression from dominance to submission" (1994:273). The authors report that more significant predictive values were obtained by including a measure of activity levels but only in the case of female puppies. Similar predictive difficulties have been reported concerning the value of puppy tests used to help select working dogs (Dietrich, 1984; Wilsson and Sundgren, 1998). Recently, however, Slabbert and Odendaal (1999) reported significant predictive correlations by testing dogs at different ages. In particular, retrieve test scores performed at 8 weeks and the scores of aggression tests performed at 6 and 9 months yielded highly significant predictive values. In combination, the three tests accounted for the prediction of 81.7% of unsuccessful police-dog candidates and 91.7% of those dogs successfully trained for police-dog service.

Perhaps, assessing approach-withdrawal tendencies, emotional arousal (especially fear) and reactivity levels, behavior thresholds, and recovery rates following fear- or aggression-eliciting stimulation at different ages might provide more predictive information about future agonistic tendencies [see Krushinskii (1960), Schneirla (1965), Martinek and Hartl (1975), and Goddard and Beilharz (1986)]. Sympathetic arousal and recovery as measured by changes of heart rate may provide a predictive indicator of temperament, especially with regard to the fear-withdrawal dimension (Fox, 1978). However, even these possibly more stable and heritable indicators undergo significant change over time as the result of developmental consolidation, biological alterations (e.g., hormonal changes), and learning. Nonetheless, assessing behavioral thresholds controlling fear/flight tendencies (passive defensive reactions) and anger/aggression tendencies (active defensive reactions) may provide an objective means for describing and predicting social aggressive behavior in dogs. As discussed in a previous section (see *Behavioral Thresholds and Aggression*), dogs at risk of developing an aggression problem may exhibit at an early age a relatively high response threshold to fear-eliciting stimulation (slow to flight), while showing a relatively low threshold for anger arousal and aggression (quick to fight). As a result, when faced with provocative stimulation, the *excitatory* or active defensive threshold may be triggered before the *inhibitory* or passive defensive threshold is reached. Puppies exhibiting lowered response thresholds for both fear (quick to flight) and anger (quick to fight) are probably at a significant risk of developing serious adult aggression problems involving rage. This risk may be particularly strong in cases in which both fear and anger are evoked at the same time, with the one motivationally cross-associating

and fusing with the other. Under the simultaneous evocation of intense fear and anger, predisposed puppies may exhibit rage (a composite response of escalating fear and anger). As a result of the repeated or traumatic collision of fear and anger, abnormal aggressive behavior may develop (see *Experimental Neurosis* in Volume 1, Chapter 9). As adults, the conditioned or unconditioned elicitation of fear may serve to trigger (rather than inhibit) aggression, thereby releasing a cascade of escalating events in which fear and anger converge motivationally in the expression of uncontrollable rage. In support of this functional etiological analysis, many owners of adult dominance aggressors report a considerable admixture of fear and aggression in the behavioral histories of their dogs.

In addition to puppy tests, temperament evaluation procedures of various kinds have been devised to assess behavioral tendencies in adult dogs. Although the value of puppy temperament tests for predicting adult dog behavior has been challenged, temperament tests for assessing behavioral tendencies of adult dogs are still widely employed and used to help assess and predict future behavior. For example, these tests are often performed to evaluate and certify dogs used in nursing homes to comfort residents and to perform animal-assisted therapy (Fredrickson and Howie, 2000). Unfortunately, most temperament assessment procedures and tests have not been statistically validated for reliability or predictive value (Goodloe, 1996). In a study involving shelter dogs (N = 9) being selected for service work, Weiss and Greenberg (1997) were unable to find a correlation between their performance on an 11-part selection test and subsequent trainability for a service-related task (retrieving). Among tested parameters, they found that fearful submissive tendencies persisted from the initial testing phase into the training and evaluation phases of the study. Interestingly, in one case, a dog passed all test items and was ranked *excellent* but was unable to complete the training phase as the result of excessive excitability and "dominance" behavior. This latter finding underscores the unreliability of inferences about the future absence of some behavior or tendency based on its nonoccurrence during testing, especially in the case of tests not designed to specifically identify and measure its occurrence. In principle, the mere *absence* of some behavior is not a valid indicator of reliability for tests designed to predict behavior, at least insofar as one wishes to avoid running afoul of the *dead-dog rule* (see Chapter 2). Just because some behavior has not been observed to occur in the test or working situation does not rule out its possible occurrence in the future. At best, temperament tests can only reliably predict behavior or analogs belonging to the same general class of behavior observed and assessed during the test. Presumably these identified behaviors are statistically correlated with success in the performance of activities for which the test is applied (e.g., companion dog, therapy dog, or service dog), but even these important data are generally still lacking.

Exploratory efforts have been carried out to validate some behavior tests for identifying tendencies associated with aggression problems. For example, Netto and Planta (1997) have devised a temperament test involving 43 subtests used to identify and assess aggressive behavior in dogs. They report that the test yields significant validation (when compared with the results of owner questionnaires) and a high degree of reliability between test and retest scores involving interspecific attack and snapping directed toward human targets. However, some significant variations were identified between test and retest scores in the case of dog fighting. Intraspecific aggression appears to increase after retesting, suggesting that the dogs may have become less inhibited as the result of increased familiarity with the test area—a finding that has obvious parallels with Wright's study discussed previously. Van der Borg and coworkers (1991) devised and evaluated a series of tests for identifying dogs prone to exhibit a variety of common behavior problems, including aggression. The researchers found that the behavioral tests provided a better means for detecting potential problem behaviors than did the opinions of shelter staff. The opinions of shelter staff were 33% successful in predicting potential problem behaviors, whereas the tests proved to be 74.7% successful in predicting potential problems in adopted dogs.

Prevention

Puppies exhibiting incipient signs of aggression should be identified and referred for appropriate training and behavior modification. Behavior problems caught early enough are often highly responsive to training and therapy; however, as time goes on and they become established, significant change may become progressively harder to achieve: *organization impedes reorganization.* Puppies at high risk are those described by their owners to be difficult, testy, or reactive (quick to show fear or aggression); they are commonly hyperactive, possessive (growl and snarl) over food and toys, competitive and reactive to punishment, engage in habitual *stealing* of forbidden objects that they may then protect or stiffen over, aggressively resist routine grooming or handling efforts, engage in excessive or hard mouthing when touched, and resist basic training efforts. Members of a group at particular risk are those that resent touch and handling (e.g., being picked up) and exhibit other signs of contact aversion. Such puppies may resent even the most gentle petting and handling. While the aforementioned oppositional tendencies should prompt concern, not all puppies exhibiting reactive or competitive behavior necessarily grow up to become aggressive adults; nonetheless, it is important that owners presenting such behavior complaints be encouraged to seek appropriate professional training and counseling for their puppy.

First and foremost, behavior problems are prevented by establishing a human-dog bond informed by a high degree of affection, communication, and trust, that is, interactive harmony. Ultimately, though, preventing aggression problems can be realistically achieved only by genetically improving dogs for close association with people. Genetic improvement depends on selecting and breeding dogs that are less likely to produce overly aggressive offspring. In addition to improved genes, however, dogs need effective training, socialization, and the satisfaction of their basic social and biological needs. All of these considerations are indispensable for ensuring a dog's successful adaptation and the avoidance of adjustment problems—insofar as they are avoidable. Again, in terms of preventing or managing serious aggression problems in vulnerable dogs, considerable benefit can be achieved by initiating early and sustained integrated compliance training and incorporating various behavior modification efforts as needed over the course of the dog's life. Such training helps to modulate behavioral thresholds, reduces interactive frustration and irritability, enhances communication and affiliative cooperation, and promotes affection and relaxation. Finally, such training and socialization significantly improve a dog's overall quality of life, while enhancing the relationship between the owner and dog—the ultimate goals of cynopraxic therapy.

Appetitive and Elimination Problems

For a dog, when he comes to a rosebush or some other shrub, though he cannot urinate, yet he will lift up his leg and make a pretense of doing so.

GEOFFREY CHAUCER, *Canterbury Tales* (1394/1929)

PART 1: APPETITIVE PROBLEMS

EXCESSIVE EATING AND OBESITY

Malnutrition resulting in excessive weight gain or loss occurs when dogs either ingest too much or too little food for their biological needs. If dogs ingest more calories than they need to support biological functions, the excess is converted and stored as fat. As the result of habitually eating more food than is required, the dog's body weight will gradually increase over time. On the other hand, if dogs eat too little food for their needs, fat reserves are gradually depleted and their body weight will decrease.

Definition and Incidence

As in humans, obesity is a common problem among dogs. Obesity can be defined as a condition in which fat reserves accumulate to a point such that the dog's health may be adversely impacted. The extent of the problem has been estimated to affect between 24% and 34% of the dog population (Markwell, 1990), although one practitioner reported that as many as 44% of the dogs visiting an Austrian

small animal clinic were overweight [see Edney and Smith (1986)]—an estimate echoed by Morris and Beaver (1993), who indicate that 44% of the overall companion animal population may be overweight. A dog is considered obese when its body weight exceeds its ideal weight by 15% to 20%, but even excess weight 10% above a dog's ideal weight can have significant health and quality-of-life implications. A simple way to judge roughly whether a dog is underweight or overweight is to observe and palpate its ribs (Sibley, 1984). If a dog's ribs are visible, this is a sign of malnutrition in the direction of inadequate caloric intake, whereas, if the ribs cannot be felt, the thick layer of fat indicates that the dog may be eating too much for its energy needs. Significant evidence suggests that excessive weight gain early in life adversely influences osteoarthritis associated with hip dysplasia. Keeping a dog's weight at optimal levels appears to reduce the severity of radiographic signs of hip osteoarthritis in adult dogs (Kealy et al., 1997). Recently, Impellizeri and colleagues (2000) reported promising evidence suggesting that weight control in adult dogs can significantly reduce observed signs of lameness associated with hip osteoarthritis. The nine dogs, estimated to be 11% to 12% over their ideal weight, lost 11% to 18% of their initial weight while fed a reduced-calorie diet for 10 to 19 weeks. As a group, they showed a steady reduction in lameness over the course of the dieting period.

Feeding and Obesity

Dogs gain weight because they eat more food than they need to satisfy their biological and energy requirements. Of course, this is largely an avoidable problem, since owners control what dogs eat. The causes of overfeeding are varied. Puppy owners are often under the false opinion that a plump puppy is a more healthy puppy and more likely to attain its full size. Consequently, they may overfeed the puppy or supplement its diet in various ways to cause it to eat more than it needs. These efforts may include frequently changing diets, enhancing the ration's palatability by adding canned food or table scraps, and feeding between-meal treats. In some cases, owners may feed a premium diet containing highly digestible food in excessive amounts; however, even in cases where a dog is fed according to the manufacturer's instruction, the dog may still gain weight. Breed, sexual status (spayed or neutered), and health may affect metabolic efficiency or energy expenditure. In addition, food needs vary with activity levels (exercise) and seasonal influences on thermoregulation. Also, despite owner protests otherwise, a little detective work often reveals that a dog is getting additional sources of food besides what is provided in its bowl. For example, some owners may use biscuits to reward good behavior and inadvertently cause their food-trained dogs to become overweight. Small food rewards are usually adequate for training purposes. Further, problems can be avoided by subtracting the amount of food given during training activities from the dog's daily ration. In large families, dogs may receive additional food and treats by begging from different family members. Since only a very small amount of excessive food can result in significant weight gain over time, such incidental sources of food may represent a significant cause of obesity.

Overeating may also result from social facilitation when dogs are fed in close proximity of one another (James and Gilbert, 1955). In some cases, however, close feeding proximity may result in appetitive inhibition and weight loss, especially in the case of dogs that do not get along together on peaceful terms. Mugford (1977) found that feeding a group of dogs on an ad libitum basis (free feeding) significantly curtailed social facilitation, with dogs only infrequently eating together if they had food continuously available to them. In addition to social facilitation, eating excesses may also result from compulsive conflict. For example, Fox (1962) describes an unusual case involving a 12-year-old male Welsh terrier that developed a compulsive eating habit (polyphagia) after a cat was introduced into the household. When in the presence of the cat, the dog ate five times more food than normal. Within 6 weeks, he was grossly overweight and exhibited persistent flatulence. Fox theorized that the dog's excessive eating when near the cat was the result of a summation of appetitive and attention-seeking moti-

vations; that is, in the presence of the owner, attention-seeking behavior and eating behavior became motivationally cross-connected in a compulsive manner.

Metabolic Considerations

In many ways, obesity appears to be more of a metabolic problem rather than an eating problem. Aside from the possibility of a systemic disorders (e.g., hypothyroidism), some dogs simply appear to possess a more efficient metabolic system. As a result, such dogs may be more prone to gain weight because they are better equipped to digest and assimilate more of what they eat while expending a minimal amount of energy doing so. Naturally, dogs with an efficient metabolism would tend to deposit, store, and conserve more fat than counterparts possessing a less efficient metabolism. Evolutionary pressures appear to favor the development of a highly efficient metabolism. A highly efficient digestive and metabolic system would make the most competent use of available food. The storage of fat reserves during times of plenty would help to ensure the animal's survival when faced with adverse conditions of food scarcity or starvation. Under natural conditions, this hypothetical protective mechanism is functional and very useful, since food is not easily and consistently obtained; however, under the superabundance and variety (cafeteria-diet effect) often associated with the domestic situation, dogs may ingest far more food than is necessary for their basic biological needs. The net result is excessive weight gain. In addition to depositing and storing fat, under adverse foraging conditions an animal's metabolism may undergo changes toward becoming more efficient. This adaptive mechanism appears to enhance metabolic efficiency under conditions of starvation [see Brownell et al. (1986)], perhaps helping to explain the tendency of animals and persons to gain weight on a lower-calorie diet or to regain lost weight and more when they go off the diet.

Energy is primarily expended in one of two ways: exercise and heat production. The majority of energy expended by the body is consumed by thermoregulation, with approximately 70% to 85% of caloric energy being used to maintain resting-state metabolism, and the digestion-assimilation of nutrients (Carlson, 1994). Durrer and Hannon (1962) reported a significant relationship between environmental temperature, food intake, and weight gain or loss among a group of Alaskan huskies. Despite eating nearly twice as much food during the winter than during the summer, the dogs tended to lose weight during the cold Alaskan winter months—weight they gained back again during the much warmer summer months. Even under the influence of more modest seasonal temperature changes (Florida), dogs tend to eat significantly less in the summer than in the winter (Rashotte et al., 1984). Although exercise is very beneficial in terms of promoting general health and a sense of well-being, physical activity appears to account for a relatively small number of calories burned. Consequently, weight-loss plans usually emphasize the input (food ingestion) side of the weight problem rather than the output (e.g., exercise) side, but both food restriction and exercise are necessary for effective weight control. In addition to quantity, the digestibility and nutritional density of the food also plays a significant role.

Neurobiological Control of Hunger and Satiety

Another potential cause of overeating is a physiological dysfunction or interference of hunger and satiety signals. Traditionally, opponent set points in the hypothalamus were believed to regulate food intake by inducing hunger (lateral area), on the one hand, and triggering satiety (ventromedial area), on the other (Johnson et al., 1962). Although the lateral hypothalamus (LH) appears to mediate hunger and appetitive preparatory activities via seeking-system circuits, the role of the ventromedial hypothalamus (VMH) in mediating satiety has been found to be more complex than previously believed. In fact, both hunger and short-term satiety signals instructing animals to stop eating probably originate within the LH (not the VMH), whereas the long-term *energy balance system* responsible for regulating food intake appears to originate within the VMH (Panksepp, 1998). Together, these areas of the

brain modulate many aspects of the short- and long-term appetitive-seeking system, thereby keeping energy input and energy output in balance. Under certain conditions, dysregulation of hunger-satiety control may occur. For example, incentive motivation derived from the ingestion of novel or highly palatable food items may overshadow or confound satiety signals, thereby causing a dog to eat more than it needs. Bradshaw and Thorne (1992) suggest that overeating (and undereating), resulting from the ingestion of novel foods, may occur because dogs are unable to predict the nutritional value of the unfamiliar food and do not "know" when to stop eating:

> Most mammals stop eating long before the equilibrium state of the body has been restored, the delay being due to the digestion of many key nutrients, so meal-end must be controlled by some signal that sufficient food has been taken into the stomach. This can only be accurate if the end product of digestion can be predicted, which normally means that the food is a familiar one. Thus both cats and dogs may under- or over-eat if presented with a new food, particularly if it is of a new type; for example, semi-moist food can induce this kind of temporary error when first introduced into the diet. (121)

Whatever the causes, the ingestion of novel food items is believed to facilitate obesity. In the laboratory, a common means to induce obesity is to provide animals with a "cafeteria diet" consisting of a variety of high-energy and palatable food items, thus causing hyperphagia and rapid weight gain (Rothwell et al., 1982).

Significant research has been focused on the role of the neurotropic hormone leptin in the etiology of obesity (Friedman and Halaas, 1998; Friedman, 2000). Leptin is produced by fat tissue and exerts an influence on appetite and fat reserves via leptin receptors located in the hypothalamus. Most of the leptin research has been carried out on mutant obese mice possessing a defective gene needed to produce leptin. When obese mice are injected with leptin, they rapidly lose fat reserves (30% in 2 weeks) by not eating as much and by increasing energy expenditure. In contrast to weight loss achieved by dietary restriction, where both fat reserves and muscle tissue are lost, losses produced by leptin injection specifically target eating behavior and reduce weight by decreasing fat reserves only. Obviously a factor in the regulation of appetite and weight gain, leptin itself may not represent a cure for obesity, however. Obese people, for example, appear not to be lacking in leptin hormone production (in fact, they typically possess much higher levels than lean counterparts) or lack hypothalamic leptin receptors (Panksepp, 1998). The presence of high levels of leptin in obese people suggests that they may produce increased hormone in an effort to compensate for a defect somewhere in the satiety-signaling system (Friedman et al., 1995). The inability of leptin to signal satiety and inhibit eating may be mediated by another gene (SOCS-3), whose expression is turned on in the presence of high leptin levels and inhibits the action of leptin on satiety control centers (Bjorbaek et al., 1998). Finally, Friedman and colleagues have found that dieting results in lowered levels of leptin, perhaps helping to explain the increased appetite, slower metabolism, and weight regain associated with on-again, off-again dieting. Although not a likely cure for obesity, the researchers suggest that leptin may eventually prove beneficial as a means for reducing appetite and helping to maintain weight loss after dieting.

Drinking behavior appears to be under the influence of serum osmotic pressure and blood volume, with drinking being stimulated when serum osmotic pressure rises between 1% and 3% (Wolf, 1950). These changes in osmotic pressure are detected by osmoreceptors in the anterior hypothalamus. Drinking is stopped by a combination of signals, including stomach sensations, dilute blood, and the completion of drinking movements (Johnson et al., 1962).

Owner Attitudes

Kienzle and colleagues (1998) learned that obesity in dogs is affected by the owner's attitude toward the dog and food. They performed a study comparing the personal characteristics and rearing practices of owners of obese dogs with owners of normal dogs. The researchers found that obese dogs were often treated as *fellow humans* by their owners. Also, the owners of obese dogs were often

overweight themselves because of the same lifestyle shortcomings that caused their dogs to become overweight:

> The results of this survey indicate that owners of obese dogs tend to interpret their dog's every need as a request for food. It appears that this is due, in part, to a transfer of their own health and eating habits, including a certain laziness and a lack of appreciation of the dog's nutritional and health requirements. In counseling these owners, they should be encouraged to respond to the dog's requests for attention not always with food, but more frequently with physical activities, such as brisk walks or regular play sessions. There will be benefit for both dog and owner. (2780S)

Inappetence and Anorexia

Dogs sometimes lose weight because of inappetence. Although appetite loss is often associated with medical problems, and should be brought to a veterinarian's attention, anorexia (cessation of eating) is frequently the result of psychogenic causes such as anxiety or separation distress. The suppression of appetite as the result of anxiety can represent a significant obstacle for counterconditioning and training efforts using food. As already mentioned, separation-anxious dogs exhibit a significant loss of appetite when separated from their owners. When left in a kennel for a long time, such dogs may suffer significant weight loss stemming from anorexia.

Dogs may become problem eaters as the result of improving the palatability of ordinary food in order to increase their willingness to eat it. Not only do enhanced diets encourage overeating and possessiveness around the food bowl, they may stimulate dogs to seek even more novel foods. Regardless of what they are given, such dogs may not remain satisfied for very long before they start holding out for something even better. Also, dogs fed savory or varied food items in order to improve appetite may inadvertently learn to manipulate the owner by begging or by abstaining from eating for progressively longer periods. Such dogs may become finicky and refuse to eat ordinary dog food when it is offered to them, especially if it is not mixed with a tasty incentive. A finicky dog can learn to eat regular food again, but only if its owner stays firm and does not yield to the dog's importunate demands for something better. Another possible cause of anorexia in dogs is taste aversion (Houpt, 1982). Following a serious sickness involving nausea, a previously acceptable food associated with acute internal distress may be avoided after the dog recovers.

Pica and Destructive Behavior

Destructive behavior is driven by diverse motivational considerations. A brief inventory of the pertinent factors, includes anxiety, boredom, frustration, attention seeking, nutritional deficiencies, insufficient exercise, hunger tensions, and inadequate training. In addition, destructive behavior is often associated with common diagnostic entities such as separation distress and hyperactivity. Obviously, it is important to assess each case carefully and to determine the likely causative factors involved before drawing premature conclusions and possibly implementing inappropriate or ineffective training. This caution is particularly important with regard to destructive behavior associated with hyperactivity and separation distress (boredom, frustration, and anxiety) and other reactive emotional states.

The term *pica* [after the Latin name for the magpie (*Pica pica*)—a bird reputed to eat a wide variety of things] is used to designate nonnutritive eating of things like cloth, wood, plastics, stones, dirt, or just about anything else a dog can seize with its mouth and swallow. A very common form of pica is grass eating. The causes of grass eating are still unknown but have attracted a range of opinions from a vegetable dietary supplementation, gastric pH regulation, natural purge for worms, and a learned way to induce vomiting when a dog feels nauseous (Beaver, 1981) to perhaps a natural remedy for gastrointestinal irritation (McKeown, 1996). Another common pica habit is chewing and eating stones—which may result in excessive dental wear and gastric obstruction (Fox, 1963). In some cases, this habit may exhibit a compulsive character, as the following anecdote reported by Unwin (1994) seems to indicate:

> The patient was a young male basset hound. Diagnosis was not difficult—he rattled when he moved. After his third gastrotomy I took him out for a walk. Although wobbly from the anaesthetic, when we approached a gravel path he brightened up and attempted to prize a stone out of the ground. (511)

Like other forms of pica, it has been speculated that stone chewing may be related to a nutritional deficiency or malabsorption problem, but this connection has not been experimentally demonstrated. Some puppies and dogs are highly attracted to a variety of household items (e.g., clothing, tissues, paper, toys, carpet matting)—items that may be ingested and cause gastric impaction or bowel occlusion requiring veterinary surgical intervention. Such animals need to be carefully supervised or restrained to prevent such behavior until the underlying causes can be identified and appropriate behavior modification carried out.

Pica is sometimes associated with an underlying medical condition, and therefore its evaluation should include a veterinary examination, especially in cases that involve the ingestion of large of amounts of nonnutritive material. Commonly cited medical causes of pica include a variety of gastrointestinal disorders, including parasitic infestation. Other possible causes of pica include toxins, metabolic disorders, nutritional deficiencies, and neurogenic pathology. Lead toxicosis should be considered as a possible factor in cases where a history of chewing on wood painted with lead-based paint is evident. Lead may also be ingested by puppies that chew or eat newspapers and magazines (Hankin et al., 1974), although such sources of contamination are probably less significant today than they were in the past. Lead, which is a common source of poisoning, may be associated with hyperkinesis, especially in dogs known to have been exposed to lead at an early age. Other behavioral signs of lead poisoning include anorexia, hyperexcitability, compulsive barking, champing fits, convulsions, muscular spasms, and increased sensitivity to touch (Zook et al., 1969). Although pertinent statistics are not available for dogs, 70% to 90% of children testing positive for lead poisoning also have a history of pica (Feldman, 1986).

Some forms of compulsive pica may stem from a malfunction of the limbic system. Bilateral ablation of the temporal lobes in monkeys results in compulsive orality: "The hungry animal if confronted with a variety of objects will, for example, indiscriminately pick up a comb, a bakelite knob, a sunflower seed, a screw, a stick, a piece of apple, a live snake, a piece of banana, and a live rat. Each object is transferred to the mouth and then discarded if not edible" (Kluver and Bucy, 1937:353). The researchers characterized the condition as a "psychic blindness," leaving the animals unable to determine, in advance of placing the item in the mouth, whether it was edible or not.

Nutritional Deficiency

Various nutritional hypotheses have been proposed to explain destructive chewing and other forms of inappropriate appetitive interest or ingestion. Studies of children have found an apparent causal connection between pica and nutritional deficiencies, particularly involving trace metals like zinc and iron. The most frequently cited cause of pica in humans is iron deficiency. For example, among persons exhibiting mental retardation, the frequency and severity of pica are directly correlated with the degree of iron deficiency. In the case of laboratory rodents, iron-deficient rats exhibit 50% lower levels of dopamine (D2) receptors in various areas of the brain. Some authorities have speculated that reduced dopamine neurotransmission is an instrumental neural chemical substrate underlying increased levels of pica activity. Following this line of reasoning, Singh and colleagues (1994) tested the effect of two drugs that have opposing effects on dopamine, one depressing dopaminergic activity (thioridazine) and the other stimulating it (methylphenidate). When given methylphenidate, mentally retarded persons with pica exhibit a sharp decrease in the habit to negligible levels while showing a symmetrically dramatic increase in pica when treated with the D2-antagonist thioridazine. In cases where malabsorption of iron is suspected, vitamin-C supplementation may be beneficial, since ascorbic acid appears to facilitate the absorption of iron (Levine et al., 1999).

Reactive Emotional States and Destructiveness

Dogs appear to engage instinctively in chewing and digging when they are restrained, frustrated, or distressed in an effort to break free or otherwise resolve a stressful situation. For wild canids, chewing and digging are also valuable means for exploring the environment and achieving control over the natural resources needed for survival (e.g., burying and recovering caches of food, uncovering cool earth to enhance thermoregulation, den construction, and foraging on plant matter). Under domestic conditions, these tendencies to chew and dig may become destructive and problematic when they are directed toward personal belongings and carefully planted gardens. In addition, domestic dogs may fall under the influence of various stressors and emotional influences that trigger maladaptive chewing and digging activity. For example, separation anxiety is considered a leading cause of destructive behavior occurring in an owner's absence (Lindell, 1997). Separation anxiety should always be considered as a possible cause in cases were destructive behavior is directed toward door frames, nearby carpeting, and window casings. Such behavior may also be driven by barrier frustration evoked by the owner's departure or outdoor activities (e.g., passing dogs or other animals). Other sources of distress include fear and boredom. Thunder-phobic dogs are prone to scratch and bite on doors and walls when left alone during a storm. Some storm-thunder-phobic dogs routinely flee into closets only to scratch and chew through drywall, sometimes injuring themselves in the process. Finally, simple boredom has been frequently implicated in destructiveness (Voith, 1980; Turner, 1997).

In cases where a stress-related etiology is suspected, the various sources of stress must be identified and addressed with appropriate conditioning, training, and environmental change. Separation-anxious dogs, for example, need help learning to cope with loneliness and distress at separation, frustrated dogs must learn to accept constraining situations imposed upon them, fearful dogs must be systematically desensitized, and bored dogs need to be provided with alternative means for obtaining the stimulation that they crave. Once the underlying causes are alleviated, a dog's destructive tendencies often undergo spontaneous reduction without further training. In some cases, however, a dog may acquire a refractory appetite for destructive activity and consequently fail to stop engaging in the habit, even though the original causes have been removed. Destructive chewing, in particular, may easily develop into such a "vice." In such cases, the object continues to attract the dog's chewing activity and may require inhibitory training or aversive counterconditioning and the redirection of chewing activity into more acceptable outlets.

Pica and Scavenging

Scavenging is a normal canine activity that has served dogs' survival in close habitation with humans for many thousands of years. Current theories of domestication underscore the significance of scavenging for the mediation of close contact between semiwild protodogs and early humans (see *Interspecific Cooperation: Mutualism* in Volume 1, Chapter 1). Most dogs show some degree of interest in scavenging, but some dogs may become virtually obsessed with finding and eating the most unappealing things, at least with respect to the human eye and palate. Scavenging dogs can be extremely frustrating for their owners, making walks a harrowing lunge and yank from one thing to another. Sticks and leaves, rocks, tissues, animal carrion, bits of garbage, everything seemingly draws the dog's fleeting attention. This habit is particularly common in excitable and hyperactive dogs, especially young sporting dogs like the golden, Labrador, and Chesapeake Bay retrievers. The habit should be carefully managed, since improper training could very easily cause a nuisance to escalate into a more serious problem. Such dogs may become progressively possessive and defensive about their prizes, perhaps culminating in embarrassing public affrays over scavenged objects. Many dog owners have been seriously bitten attempting to pry a tissue or piece of plastic wrap from the mouth of their scavenging dog. Possessive aggression problems are frequently traced to competitive interaction over scavenged or

stolen items and the punitive removal of such things from the dog's mouth. The risk of aggression is increased by chasing after a dog that has managed to grab something, especially if it is cornered and forced to release the object. Such activities, while occasionally necessary for a dog's safety, should be avoided whenever possible. Instead of forcefully removing objects from a dog's mouth, the owner should train the dog to trade its prize for a reward.

COPROPHAGY

In many species, such as the rabbit, coprophagy (stool eating) is a normal ingestive behavior that provides a variety of vital nutrients, including B-complex vitamins (Soave and Brand, 1991). Denying rabbits, for example, access to fecal droppings produces nutritional deficiencies and health problems, and, in the case of young rabbits, retards normal growth and weight gain. In the case of rats, 5% to 50% of their fecal output is eaten, providing them with an important source of thiamine and vitamin K. Although dogs do not need to eat feces for good health, when they are fed a thiamine-deficient diet, dogs will engage in coprophagy to stave off physical symptoms and attenuate neurological signs of thiamine deficiency, at least temporarily (Reed and Harrington, 1981). In horses, foals under 20 weeks of age show a preference for their mother's feces, which they eat (Crowell-Davis and Houpt, 1985). A similar phenomenon exists in rats. Rat pups appear to be attracted to maternal feces in order to obtain deoxycholic acid, a chemical that protects them against enteritis and facilitates the digestion and absorption of fatty acids needed for the manufacture of myelin. Finally, equine coprophagy may provide foals with various nutrients (e.g., vitamins and protein) and beneficial bacterial flora needed for digestion (Crowell-Davis and Caudle, 1989). Perhaps similar pheromones and biological benefits are obtained by puppies when they eat feces—a hypothesis that remains to be tested.

Mother dogs instinctively elicit elimination and ingest their puppies' excrement from birth to approximately 3 weeks of age. Particularly fastidious mothers will sometimes continue to "clean up" after their puppies long after week 3, however. Adult males will also ingest feces produced by young puppies. Among wolves, mothers only ingest "milk scats" and refrain from eating fecal material after the puppies begin to eat meat at approximately 3 to 4 weeks of age (Allen, 1979). Although dogs of all ages may show the behavior, coprophagy is particularly prevalent among puppies and young dogs between 4 and 9 months of age. Besides eating their own feces (*autocoprophagy*), some dogs ingest the feces of other dogs and animals (*allocoprophagy*), especially cat and horse droppings. Most dogs actively explore the droppings of other dogs and animals, but, for some dogs, something in the feces is sufficiently compelling and attractive for them to go further and eat it. The texture and smell (taste) of the feces appear to be significant factors. Many coprophagous dogs are particularly attracted to frozen *poopsicles* or firm stools. Such dogs rarely eat soft or poorly formed stools and are less likely to ingest stools that have been rendered objectionable through dietary manipulation or tainted by various repellents.

Coprophagy is considered normal among puppies and represents a small health risk to the offending puppy eating its own feces (Hubbard, 1989), but eating the feces of other dogs may cause parasitic infections (e.g., coccidiosis) or increase a puppy's risk of coming into contact with viral pathogens (parvovirus) shed in the feces. Despite reassurances, owners are often disgusted with the habit and may be unwilling to tolerate it. Many persistent coprophagous dogs have been given up for adoption as a direct result of stool-eating behavior. The problem is especially intolerable in situations where a dog comes into close contact with children, who may be licked on the mouth by the dog. Sadly, some owners may even seek euthanasia in refractory cases—an outcome recommended by some authorities in cases in which the owner's "bond with their is dog irreparably damaged" (McKeown et al., 1988:850) by the habit. However, euthanizing a dog because of coprophagy seems to be a rather extreme and questionable practice.

Putative Causes of Coprophagy

The exact causes of the habit are unknown, but several etiologies have been described. There appears to be some connection between excessive coprophagy and nutritional deficiencies, stress, boredom, unsanitary rearing conditions, and restrictive housing.

Environmental Stress

Overly restrictive or isolatory confinement has been correlated with a higher incidence of coprophagy in dogs. Houpt (1982), for example, has reported that dogs exposed to excessive isolation (kept in kennels or basements) are more likely to engage in the habit than dogs kept in close contact with people. Beerda and coworkers (1999) reported evidence suggesting that restrictive confinement may represent a significant factor in the etiology of coprophagy. In addition, they reported that pica (gnawing behavior) similarly increased among dogs housed under restrictive conditions, suggesting that both coprophagy and pica may be influenced by environmental stress. The dogs (beagles) in the study were first housed under unrestricted (outdoor) conditions before being moved to more restrictive (indoor) housing conditions. The procedure suggests that the causative variable may not be restrictive/isolatory confinement per se but rather points to the possibility that the stressful change and adaptation associated with the transition from outdoor to indoor housing conditions may play a role in precipitating coprophagous activity. In conclusion, at least in some cases, coprophagy may be part of a general pattern of behavioral adaptation to stressful housing conditions, especially those involving increased restriction and social isolation.

Anxiety Reduction and Attention Getting

Anecdotal correlations between coprophagy and various psychological states, such as anxiety reduction and attention seeking, have been suggested but not convincingly demonstrated. Campbell (1975), for example, argues that coprophagy is often exhibited as an anxiety-reducing response acquired as the result of inappropriate punishment during house training or in association with normal fecal interest and exploration. According to his theory, coprophagous dogs choose to eat their feces because it eliminates the *evidence* and the threat of punishment. However, instead of being successful, the act is followed by additional punishment, more anxiety in the presence of feces, and, consequently, more stool eating. Hart and Hart (1985) have speculated about a similar—but opposite—vicious circle. They have noted that some cases of coprophagy may be calculated to attract the owner's attention; that is, eating feces is interpreted as a form of attention-seeking behavior:

> Owners may react emotionally to the sight of their dogs going after feces, and a dog may pick up this reaction as a means to garner additional attention. (107)

Nutritional Causes

A common assumption holds that coprophagy is related to some sort of nutritional problem or deficiency. These theories generally emphasize one of two possibilities: (1) coprophagy is a search for nutrients lacking in a dog's diet or (2) the habit is motivated to consume undigested nutrients passed into the feces. Vitamin-B deficiencies have been frequently implicated. In this regard, Reed and Harrington (1981) note that canine fecal microbial activity synthesizes thiamine and other B vitamins, with coprophagy providing some relief to thiamine-deprived dogs. Landsberg and colleagues (1997) summarized the results of an unpublished study involving nine coprophagous dogs. All exhibited at least one laboratory abnormality that could explain the development of the problem. The majority of the dogs exhibited low to borderline levels of trypsinlike immunoreactivity. Some dogs exhibited abnormal folate or cobalamin levels but none exhibited abnormal fecal fat or trypsin levels. Finally, no evidence of intestinal parasites was revealed by fecal exams. One author claims rapid control of coprophagy by increasing the ration's protein and fat content, reducing the amount of car-

bohydrates, and supplementing with brewer's yeast (Cloche, 1991). Another obvious nutritional possibility to consider, and one perhaps more directly linked with a nutritional function, is that coprophagous dogs may simply be harvesting undigested food passed in the feces.

Enzyme Conservation

Besides undigested food and other nutrients, feces is a rich source of digestive enzymes and bacteria. Whether or not the ingestion of alimentary bacteria is of any benefit to dogs is not known, but some evidence suggests that digestive enzymes may play a role in the control of coprophagy. Many veterinarians and dog trainers report anecdotal success when a meat tenderizer containing papain (a proteolytic enzyme) is added to the coprophagous dog's diet. In the aforementioned report by Landsberg and colleagues (1997), the authors found that four of the nine dogs treated with a plant-based enzyme supplement responded favorably to the therapy. McCuistion (1966) argues that, as the result of living in close association with people, the dog's eating habits and sources of food have changed from a diet proportionately high in animal protein content to one high in carbohydrates and vegetable proteins. He believes these are changes that the canine digestive system has not fully accommodated.

A critical factor influencing a dog's digestive efficiency is the presence of adequate levels of various digestive enzymes specifically designed to metabolize proteins, carbohydrates, and lipids. McCuistion argues that coprophagous dogs eat feces to collect and conserve these critical enzymes, especially those involved in the digestion of carbohydrates and proteins. The theory makes some sense and, perhaps, enzyme deficiency is a relevant factor in some cases of coprophagy. After all, although dogs can survive on a vegetarian diet alone (Thorne, 1996), they are preferentially opportunistic carnivores adapted to eat and digest an omnivorous diet containing a significant proportion of animal protein. Under domestic conditions, dogs are made to eat relatively monotonous diets consisting of high levels of carbohydrate and protein content derived from plant sources. It is reasonable to suspect that some predisposed dogs may exhibit an insufficiency of digestive enzymes needed to digest such food thoroughly, enzymes that they conserve or harvest by eating their own or other animal's feces.

Wolves are particularly attracted to the viscera and contents of the gut, which they eat first—before the more protein-rich and muscled areas of their prey. The canid's predilection to eat gut contents first may have evolved as a means to obtain exogenous digestive enzymes needed to assist in the digestion of gorged flesh protein. Some dogs are particularly attracted to horse manure and apparently relish the opportunity to eat it—could they be seeking similar digestive components? According to McCuistion, some dogs appear to have suffered inadvertent physiological alterations as the result of selective breeding—changes that may reduce the production of proteolytic and other enzymes. Dogs are commonly attracted to cat feces—an interest, again, that may be related to harvesting digestive enzymes or partially digested food passed in the feces.

The enzyme theory is appealing, particularly when one considers that coprophagy is most often exhibited by young dogs. Puppies ingest large amounts of food (proportionately, about twice as much as adults) and might benefit from the supplemental ingestion of exogenous digestive enzymes and partially digested food. If nothing else, perhaps such enzymes and other active digestive aids and nutrients recycled from the stool facilitate the digestive process, making it more efficient and thorough. The central question remains, though: Does a nutritional or enzyme deficiency stimulate dogs to eat feces? Most dogs do not develop coprophagy, even when they are on a less than ideal diet or starved (Crowell-Davis et al., 1995). Also, dogs suffering from pancreatic insufficiency or malabsorption disorder may exhibit such behavior but only after becoming seriously ill and exhibiting other clinical signs of disease. These questions are enough to regard the enzyme theory with some skepticism, at least until additional research is carried out.

Counterconditioning Hypothesis

Associative learning and counterconditioning may gradually supplant an innate aversion and avoidance toward feces and replace it with an appetitive attraction. This process may be facilitated by the habitual association of feces with highly attractive sources of appetitive stimulation. For example, under unsanitary conditions in which excrement is left to lie about a nursery, puppies may be exposed to the odor of feces in combination with three potential sources of appetitive counterconditioning:

–*Food:* Eating in the close vicinity of feces may forge an associative link between its odor and food. This association may cause feces to later become inappropriately identified as a potential food item.

–*Nursing mother:* In situations where the mother is obligated to eat the feces of her young (especially after they begin to eat solid food), the puppies may smell the feces on her breath and identify the odor with food. This may be an especially potent influence in the case of hungry puppies that beg for food by sniffing and licking at the mother's mouth and muzzle. If, at such times, the mother happens to regurgitate food mixed with feces, an even stronger impression may be made—a kind of *appetitive inoculation* may occur that predisposes puppies for coprophagy. Puppies may also learn to eat feces by observing the mother eating it.

–*Exploratory play:* Finally, under filthy and environmentally barren conditions, puppies may play with and ingest feces.

Evolutionary Rationale

Some clues to the origin of coprophagy may be obtained by interpreting the habit in terms of evolutionary fitness and function. In advance of true domestication, early protodogs are believed to have followed nomadic hunting groups moving across Eurasia at the end of the Ice Age. These early dogs were probably scavengers that survived on whatever was left behind in the wake of these vast human migrations. Socially confident dogs had a distinct advantage over fearful counterparts when it came to exploiting discarded offal and garbage. Confident dogs would have been able to approach closer and stay longer near human encampments and, thereby, obtain the most nutritious portions of the refuse left behind. Eating human feces conceivably offered another advantage by providing supplementary enzymes and microbial nutrients supplementing the less than ideal omnivorous diet.

As a consequence of the vicissitudes of domestication, dogs surely fell upon hard times during their long historical journey in the shadow of early humans, at times, perhaps, having little more to survive on than garbage and feces. Eating feces and garbage during times of starvation may have been encoded over time as a genetic trait. Dogs that could subsist on such a diet would have had a distinct survival and reproductive advantage over dogs that refused to eat such things.

An old Crow story, quoted by Lopez (1978), describes habits consistent with those just outlined regarding the feeding behavior of early dogs, including the eating of refuse and human feces, when necessary. The story recounts a dialogue between a dog and a wolf debating the various advantages and disadvantages of domestic life:

> A Crow woman was out digging roots when a wolf came by. The woman's dog ran up to the wolf and said, "Hey, what are you doing here? Go away. You only come around because you want what I have."
>
> "What have you got?" asked the wolf. "Your owner beats you all the time. Kids kick you out of the way. Try to steal a piece of meat and they hit you over the head with a club."
>
> "At least I can steal the meat!" answered the dog. "You haven't anything to steal."
>
> "Huh! I eat whatever I want. No one bothers me."
>
> "What do you eat? You slink around while the men butcher the buffalo and get what's left over. You're afraid to get close. You sit there with your armpits stinking, pulling dirt balls out of your tail."
>
> "Look who's talking, with camp garbage smeared all over your face."
>
> "Hrumph. Whenever I come into camp, my owner throws me something good to eat."
>
> "When your owner goes out to ease himself at night you follow along to eat the droppings, that's how much you get to eat."

"That's okay! These people only eat the finest parts!"

"You're proud of it!"

"Listen, whenever they're cooking in the camp, you smell the grease, you come around and howl, and I feel sorry for you. I pity you. . ."

"When do they let you have a good time?" asked the wolf.

". . .I sleep warm, you sleep out there in the rain, they scratch my ears, you—"

Just then the woman shouldered a bundle of roots, whacked the dog on the back with a stick, and started back to camp. The dog followed along behind her, calling over his shoulder at the wolf, "You're just full of envy for a good life, that's all that's wrong with you."

Wolf went off the other way, not wanting any part of the life. (110–111)

Tolerance for Nausea and Taste Aversion

Of necessity, dogs feeding on refuse would have acquired a considerable tolerance for nausea and other sicknesses associated with the ingestion of spoiled or rotting food. Circumstantial support for this hypothesis comes from the difficulty of establishing taste aversions in dogs (see *Taste Aversion* in Volume 1, Chapter 6). Although some authorities have claimed to achieve positive results by using taste-aversion procedures to control coprophagy (Houpt, 1991; Landsberg et al., 1997), others have been disappointed by the procedure. Hart and Hart (1985), for example, reported "little success" (106) with taste aversion for controlling coprophagy in dogs. Similarly, Rathore (1984) was unable to obtain a lasting taste-aversion effect persisting longer than 24 to 48 hours. In Rathore's study, 10 dogs were given 6 to 10 grams of lithium chloride placed inside various kinds of meat. Not only did the technique fail to yield a lasting aversion, surprisingly, upon vomiting, the dogs actually ate the nauseant-tainted vomitus. Subsequently, untainted meat associated with lithium-chloride-induced nausea was avoided for 7½ hours—a very transient effect. Also, Hansen and coworkers (1997), utilizing a taste-aversion procedure, were unable to control dog attacks on sheep effectively. They did, however, report significant side effects, including increased aggression. Although taste aversion has been reported in a number of species, including coyotes (Gustavson et al., 1974), many dogs appear to be biologically *immunized* against this sort of learning. Bradshaw and Thorne (1992) suggest that dogs may have undergone various changes as the result of domestication that militates against such learning. Perhaps the key alteration was the development of an increased tolerance for nausea. The dogs' historical dependence on less than optimal food sources, including spoiled or rotting food (a potential source of significant nausea), may have resulted in the gradual immunization of a subgroup of the dog population against nausea and the taste-aversion effect. According to this hypothesis, dogs exhibiting an increased tolerance for nausea (evolutionary immunization) may be more inclined to eat feces.

Pro and Con Evidence

Following this line of reasoning, one would expect to find a higher incidence of coprophagy among dogs on an insufficient diet or those showing a failure to digest or absorb food properly. It is noteworthy here that coprophagy is commonly observed in malabsorption disorders or starvation. Interestingly, in this regard, Serpell and Jagoe (1995) report that dogs exhibiting coprophagy are more often obtained off the street or from an animal shelter than from other sources, suggesting that some of them may have relied on feces as a source of nutrition while struggling to survive on their own. Not all the evidence supports this hypothesis, however. In an experiment reported by Crowell-Davis and coworkers (1993), several dogs were put on restricted diets and observed for behavioral changes. Given the aforementioned evolutionary hypothesis, one might expect to find increased coprophagy under conditions of reduced caloric intake. Although restricted feeding had significant effects on activity levels and some other behavioral parameters, there was no evidence of an increased tendency to eat feces by the dogs in the study.

The absence of coprophagy in dogs on restricted diets raises some doubt about the aforementioned hypothesis, but the findings do not necessarily invalidate it. First, the level

of hunger induced by the Crowell-Davis experiment may not have been sufficient to evoke coprophagy. Second, the hypothesis does not assume that all dogs are prone to develop coprophagous habits under the influence of hunger. Third, the hypothesis does not maintain that all dogs show a tolerance for nausea but only suggests that dogs that exhibit coprophagy may possess an increased tolerance for nausea. Before any decisive conclusions can be arrived at concerning the role of domestic evolution on coprophagy, much yet remains to be learned about its etiology.

Encoded Survival Habits

Whatever the causes of the habit, the resistance of coprophagy to punitive training efforts suggests that a very compelling motivational substrate underlies its expression. Consistent with the evolutionary hypothesis already discussed, coprophagy may be one of several appetitive *survival behaviors* that have evolved to cope with the periodic adversity of starvation. Such behavior may be maintained by a very lean schedule of reinforcement, respond atypically to punishment, and exhibit relative immunity to taste-aversion procedures. Consequently, some dogs may persistently scavenge on refuse, bones, and various other nonnutritive items, despite the presence of high levels of punishment and the absence of credible reinforcement to explain the maintenance of the behavior. Perhaps, as the result of some generalized motivational state of agitation (e.g., stressful conflict, frustration, or anxiety) or social need, some vulnerable dogs may exhibit displacement survival behavior despite the absence of actual starvation. In other words, under the influence of chronic stress, scavenging may be emitted as a displacement or compulsive activity. Indeed, pica, in many cases, appears to be driven by a compulsive urge to eat feces or to find, seize, and protect the most inconsequential and nonnutritive items.

PART 2: ELIMINATION PROBLEMS

The first major training chore encountered by new dog owners is house training. Effective house training depends on watchful supervision and the provision of realistically scheduled opportunities for puppies to eliminate outdoors. Most young dogs naturally tend to concentrate the placement of elimination in places away from were they eat and sleep, and readily eliminate outdoors if access is provided to them. Ross (1950) found that puppies rarely eliminated in straw-covered sleeping areas from 5 weeks of age onward, suggesting that the habit of not eliminating in areas used for sleeping begins prior to week 5. By the time puppies are 7 to 8 weeks of age, they begin to exhibit location and substrate preferences (Scott and Fuller, 1965). Such evidence suggests that preliminary house-training efforts should be initiated by the breeder prior to placing the puppy into its new home.

Physiology, Neural Control, and Learning

Elimination is interesting from a behavioral point of view because it involves the coordinated operation of Pavlovian and instrumental mechanisms. Numerous conditioned and unconditioned digestive reflexes are triggered as soon as a bite of food is taken into the mouth. As food enters the stomach, a gastrocolic reflex is elicited that causes increased colonic motility or a *mass movement.* A mass movement is a sustained peristaltic contraction that pushes gut content through the colon toward the rectum, thereby setting the stage for defecation (Berne and Levy, 1996). The structures and mechanisms controlling elimination (defecation and urination) are composed of both striated and smooth muscle tissue. The peristaltic activity occurring on the inside of the rectum is produced by smooth muscle tissue that is regulated by the autonomic nervous system. These internal alimentary reflexes function under the influence of classical conditioning. The anal sphincter, however, is composed of striated muscle tissue that is under voluntary control and subject to instrumental conditioning. In the case of urination, urine moves from the kidneys through the ureters into the bladder. As the bladder distends, a micturition reflex is elicited, stimulating internal and external sphincter contractions and detrusor inhibition (Nickel and Venker-van Haggen, 1999). When the bladder

needs to be emptied, the internal sphincter located within the neck of the bladder is reflexively stimulated to release urine into the urethra. However, the final decision to urinate is controlled by an external sphincter regulated by cortical inhibition (Berne and Levy, 1996). For urination to occur, the external sphincter must be voluntarily relaxed—a process that is strongly influenced by instrumental learning.

In addition to pressure-sensitive bladder reflexes, the dog's urinary activity is strongly influenced by olfactory stimulation. Shafik (1994) demonstrated the existence of an *olfactory micturition reflex.* Electrostimulation of the nasal mucosa results in reduced activity within the smooth muscle of the internal urethral sphincter while producing no response in the external urethral sphincter. The researcher speculates that sniffing urine marks stimulates a readiness to eliminate, despite the absence of a full bladder.

Classical and Instrumental Learning

Both classical and instrumental learning processes interact together in the acquisition and extinction of eliminatory habits. Although reflexive interoceptive stimuli do signal an internal readiness or need to eliminate (establishing operations), these preparatory reflexes are modulated by exteroceptive or external cues that define specifically when and where elimination will take place (discriminative stimuli). Ultimately, a dog's decision to eliminate is an instrumental (i.e., voluntary) act controlled at a cortical level of organization and coordinated by limbic modulatory influences and pontine urine storage and emptying centers (Nishizawa and Sugaya, 1994):

> The cerebral cortex, limbic lobe, basal ganglia, and hypothalamus in suprapontine levels and cerebellum all function in some way which modulates the lower urinary tract function with input-output relationships to the PMC [pontine micturition center]. In this connection, the frontal cerebral cortex initiates voluntary micturition with descending input to the PMC. (169)

O'Farrell (1986) argues that elimination is under the exclusive control of classical conditioning and associated reflexive mechanisms. According to her theory, elimination need not be followed by an *external reward* to encourage the habit:

> Most owners are content if the responses are conditioned to out-of-doors stimuli and not to in-the-house stimuli, but it is possible to condition the responses to much more specific stimuli, such as the gutter or a piece of grass. The practical relevance of the fact that this learning is based on classical conditioning rather than on instrumental learning is that an external reward is not necessary. . . The owner does not need to reward successes or punish failures. (32)

Although it is true that one need not explicitly reinforce elimination habits in order to strengthen them, it does not follow that they are not undergoing instrumental reinforcement. What appears to have confused O'Farrell, causing her to confound reflexive and voluntary eliminative behavior, is a failure to recognize the role of intrinsic reinforcement in the process of acquiring house-training habits. Not all reinforcers controlling instrumental behavior are present as external rewards; in fact, many voluntary behaviors are controlled by intrinsic sources of reinforcement associated with the act itself. Elimination appears to be one of these self-reinforcing behaviors.

Punishment

O'Farrell's assessment appears to have led some behavior modifiers to the fallacious conclusion that inhibitory procedures ought not be used during house training, after all—you cannot punish a reflex. In fact, mild punishment is often very expedient for promoting house training and surely should be applied whenever a puppy or dog is caught in the act of eliminating in the house. Timing is very important when applying effective punishment. The first general rule of effective punishment is that it must occur contiguously with the act of elimination—not minutes or seconds afterward but immediately and overlapping the act itself.

Unfortunately, retroactive or noncontingent punishment is still defended by some dog trainers and is still widely practiced by dog owners (see *Noncontingent Punishment* in Volume 1, Chapter 8). Excessive and inappropriate punishment should also be avoided.

For example, the practice of rubbing a puppy's nose in its urine or feces is often carried out in conjunction with the delivery of a sharp smack to its rear end with a rolled-up newspaper. Such repulsive methods are entirely without behavioral justification, even if the puppy is caught in the act. A startling sound such as a sharp tone of voice or clap of the hands is often a sufficient deterrence.

A dog's cleanliness and responsiveness to house training represents a significant factor in its success as a domestic companion. If dogs were not able to learn to urinate and defecate outdoors on schedule, it is unlikely that they would have attained the close social proximity that they currently enjoy with people. Fortunately, the vast majority of dogs are easily and permanently house trained, often in spite of poorly organized and implemented house-training efforts. Notwithstanding the ease with which most dogs are house trained, some fail to acquire good habits in the first place or develop various behavior problems involving inappropriate elimination as they develop.

Elimination Behavior

Urine Marking

Urine marking is familiar to anyone who has ever spent time around dogs. Intact male dogs are prone to show this activity, expending large amounts of energy on the investigation of attractive spots before urinating over them. Dogs exhibit various searching activities involving sniffing, licking, and sometimes gently scrapping the ground with the front paws, as though to turn up a fresher scent located below the surface. When satisfied with their olfactory inquiry, they appear duty-bound to add a splash of their own to the community *bulletin board.* Some may become rather compulsive about the habit, urinating dozens of times until the effort is reduced to dry *blanks*—a phenomenon that Bekoff (1979) interprets as a visual dominance display. As previously noted, the marking response appears to be mediated by an olfactory micturition reflex (Shafik, 1994). Dogs tend to urinate more often when off leash than when on leash, with both male and female dogs being more likely to defecate when walked off leash (Reid et al., 1984). Interestingly, Reid and coworkers also found that purebred dogs tend to urinate more often than mixed-breed dogs.

Elimination Postures

Male and female elimination postures begin to differentiate along sexually dimorphic lines by 3 to 5 weeks of age, with some male puppies exhibiting a full leg-lift posture by 19 weeks of age (Berg, 1944). Beach (1974) found that urinary postures become sexually dimorphic by 5 to 7 weeks of age, with some male beagles using the leg-lift posture as early as week 16. The discrepancies between Berg's and Beach's observations concerning the onset of leg-lifting behavior suggest that some breed differences may exist with regard to the ontogenesis of the leg-lifting posture.

Another disagreement between Berg's earlier findings and later research is the degree of stereotypy evident in male and female elimination postures. Berg claims to have never observed a female dog elevate her leg during urination. Sprague and Anisko (1973), however describe a significantly different picture with regard to male and female elimination postures. Whereas male dogs were observed to use the elevated leg posture to eliminate almost exclusively (97% of the time), females squatted only 68% of the time, with the remaining 32% of female urinations involving some other variation, including leg lifting. The researchers identified a variety of distinct postures used by males and females to urine mark, including stand, lean, raise, elevate, flex, squat, lean-raise, flex-raise, handstand, arch, squat-raise, and arch-raise (Figure 9.1). Males tend to eliminate more frequently than females. One male dog was observed to eliminate or *pseudo-urinate* 60 to 80 times over a 3- to 4-hour period (Sprague and Anisko, 1973). Usually, females fully evacuated their bladders with one or two urinations. Another prominent difference between male and female urinary activity is its directionality. Among male dogs, urine is most often directed toward the scent of other male dogs, especially involving vertical objects, whereas female dogs tend to be less selective about the

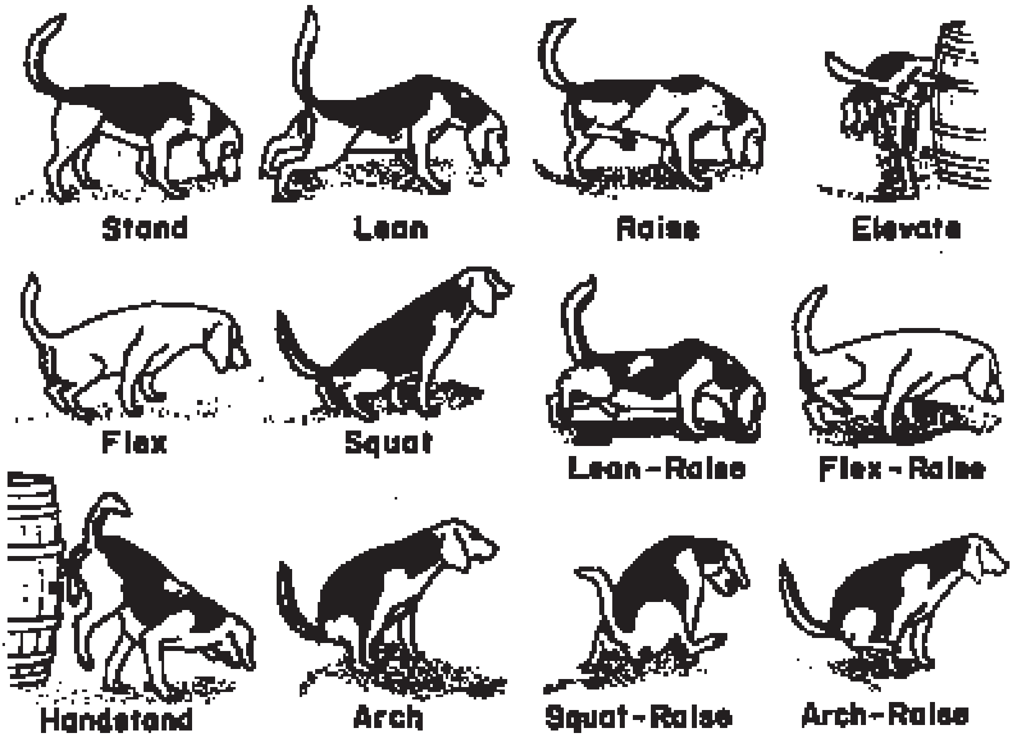

FIG. 9.1. In addition to squatting and leg lifting, dogs exhibit a variety of postures while urinating. After Sprague and Anisko (1973).

placement of urine, suggesting that urination for the female probably is restricted to a physiological function, at least during anestrus. Females were infrequently observed to sniff elimination areas before urinating. Male dogs show a definite preference toward sites frequented by females in estrus and urine-marked sites containing the scent of unfamiliar males (Dunbar and Carmichael, 1981). In addition, Dunbar and colleagues (1980) found that the stimulus value of urine to males was increased when females were injected with the estradiol and reduced when injected with testosterone.

Functions of Urine Marking

Urine marking appears to serve two primary communicative functions: (1) communication between male dogs, and (2) communication of reproductive status between males and females. These social and biological functions appear to be controlled by a hormonally modulated mechanism. Many studies have demonstrated a linkage between urine-marking behavior and the influence of endogenous hormonal activity, but this relationship is problematic. For example, Hart (1974) reported that, although castration reduced mating frequency and the duration of coital lock within 2 months after surgery, the latency and frequency of urinary marking was unaffected by castration after 5 months. Male dogs usually begin to urine mark as they reach puberty, perhaps in response to increasing concentrations of circulating testosterone (Hart, 1985). Although testosterone appears to exert an influence on urine-marking behavior, the behavior does appear to be dependent on the presence of circulating gonadal testosterone. Beach (1974) found that many dogs castrated just after birth (48 hours postpartum) or pre-

pubertally (4 to 4½ months of age) go on to exhibit the leg-lifting posture as adults. Further, he found that castration performed on adult dogs (15 to 17 months) had no observable effect on urine-marking postures.

Despite the relative independence between urine marking and a dog's reproductive status, Hopkins and coworkers (1976) found that household urine marking was gradually or rapidly reduced as the result of castration in about 50% of the dogs surveyed. Consistent with aforementioned reports, they found that urine marking away from the home was relatively unchanged in the neutered dogs:

> Several owners in the present study indicated that urine marking in relatively novel areas (e.g., sidewalks and parks) was unchanged in their dogs, whereas urine marking in the house was eliminated. These differences in castration effects between urine marking in the home and away from the home are probably related to the fact that olfactory stimuli from the urine of other dogs (which are undoubtedly the most important stimuli for urine marking) are strongest outside the home. (1110)

One way that has been proposed to resolve some of these problematic aspects associated with the hormonal mediation of urine marking is to assume that the connection is formed at an earlier point in the animal's ontogenetic development than puberty. In fact, it is known that the fetus is exposed to a significant surge of in utero testosterone secreted just before birth or immediately afterward (Hart, 1985). These androgen secretions serve to masculinize the fetus by producing sexually dimorphic changes in the neonate's brain and various biobehavioral systems. Beach (1974) found that 50% of the females perinatally implanted with a pellet of testosterone tended to exhibit malelike elimination postures. These early hormonal influences may sensitize and promote the development of certain sensory and motor neural connections that are later activated with the onset of puberty. The aforementioned variable responses to neutering, especially the persistence of urine marking in spite of prepubertal castration, may be due, in part, to the formation of such early predispositions.

Common Elimination Problems

House-training problems are a common reason that people seek behavioral advice and training regarding their dogs. Yeon and coworkers (1999) reported that 9% of the cases seen at the Cornell Animal Behavior Clinic between 1987 and 1996 (N = 1173) were house-soiling problems. Voith and Borchelt (1985) reported that approximately 20% of the overall cases presented for behavioral treatment involve elimination problems. Similar statistics concerning the relative incidence of elimination versus other canine behavior problems have been reported elsewhere (Landsberg, 1991), making inappropriate elimination the second most commonly presented behavior complaint after aggression. Few situations generate more frustration than those associated with unsuccessful house training, either because the training efforts somehow go wrong or because a previously house-trained dog begins to eliminate indoors. A variety of elimination problems have been described and classified according to descriptive and functional features (Table 9.1).

Household Urine-marking Problems

Urine marking in the home can be a persistent and damaging habit. Dogs presenting with household-marking problems are often highly excitable and reactive to novelty. Marking behavior is frequently directed toward packages brought into the home (e.g., groceries laid on the floor) or new furniture—the Christmas tree is a prime target for urinary marking. Other dogs may be stimulated to mark in the presence of visiting guests or by the presence of strange dogs coming into the home. Some dogs may mark after observing other dogs or passersby (e.g., the mail carrier) through a window. Occasionally, a particularly dominant dog might exhibit the obnoxious habit of marking people rather than objects. The behavior modifier should attempt to identify the various situations in which marking occurs and then alter the environment or introduce appropriate counterconditioning procedures.

Olfactory cues appear to play a significant environmental role in the maintenance of

TABLE 9.1. Description and etiology of elimination problems

Urine marking: Exhibited most commonly by adult, intact male dogs. Urine-marking dogs usually direct small squirts of urine against vertical objects, especially absorbent couches, chairs, and curtains. Smaller toy breeds most commonly present the problem, but large dogs also exhibit the habit.

Elimination (urination and defecation) in the owner's presence: Inadequate or inappropriate house training may cause dogs to develop a habit of eliminating indoors. A common cause of such problems is excessive crate training and failure to generalize the habit to other parts of the house.

Elimination (urination and defecation) in the owner's absence: Some dogs may abstain from eliminating indoors as long as the owner is present but will eliminate when the owner is away from the home. These cases require careful evaluation, since the unwanted elimination habit may be more directly related to separation anxiety than to inadequate house training.

Refusal to eliminate outdoors: A surprising number of dogs, especially those that have been poorly trained or not trained at all, refuse to eliminate outdoors. Such dogs often hold urine and feces while outdoors or during long walks and then race to their preferred spot upon entering the house.

Excitement elimination: Some highly excitable dogs may lose bladder control during periods of increased arousal or social stimulation. Excitement urination is distinct from submissive urination, although punishment of excitement urination may lead to submissive urination. Excitable dogs may urinate during play or at other times involving intense arousal.

Submissive urination: Young dogs and some adult dogs may eliminate when the owner returns home or enters a room where the dog is located. A submissive dog may also eliminate when guests enter or reach for it. The habit seems to be particularly prominent in females and certain breeds (e.g., the cocker spaniel, golden retriever, and German shepherd).

Fear-related elimination: Some highly fearful and reactive dogs may eliminate in response to strong fearful stimulation. Intense fear is sometimes associated with anal gland evacuation and defecation. Additionally, highly nervous dogs may develop elimination problems associated with diarrhea resulting from increased peristaltic activity.

Dietary etiology: Elimination problems can be traced to dietary causes. These include overfeeding, poor-quality food, the presence of ingredients that cause an excessive intake of water (e.g., excessive salt protein), sudden changes of food, and foods containing large amounts of fat.

Physical causes: Some elimination problems result from structural pathologies of the urinary tract or disease (e.g., renal failure, diabetes insipidus, cystitis, and obstructions). The most common sign of a urinary-tract problem is frequent urination and unusual difficulty to housetrain. Functional incompetence of the urethral sphincter is commonly treated with phenylpropanolamine (Voith and Borchelt, 1996). Urinary incontinence is sometimes observed in spayed dogs. Typically, incontinent dogs leak urine while lying down or dribble it while walking. This problem is caused by an endocrine imbalance which is often treated with hormonal supplementation (e.g., diethylstilboestrol). Older dogs often exhibit a loss of eliminatory control as part of a general aging process and deterioration of central control over the function. Some ongoing research indicates promising benefits resulting from L-deprenyl. Ruehl and colleagues (1994) have reported improvement with L-deprenyl therapy in 16 of 19 dogs with geriatric incontinence.

Genetic predisposition: Some breeds (e.g., beagles, Yorkshire terriers, and bassett hounds) appear to be more difficult to house train or more prone to lose the habit than others.

marking behavior. Dogs are attracted to areas that they have urine marked in the past, perhaps remarking those areas in an effort to keep the odor fresh. It makes sense, therefore, to carefully identify and clean such areas. In addition to scrubbing the area, the owner should also obtain cleaning agents that enzymatically break down residual deposits of urine and kill the odor-producing bacteria associated with it. Melese-d'Hospital (1996) has emphasized the importance of thorough neutralization of urine odors in the treatment of urine-marking behavior problems. Several products are currently on the market for this

purpose [e.g., KOE, Nature's Miracle, X-O and X-O plus, and ANTI-ICKY-POO (a genetically engineered combination of enzyme and bacteria designed to consume urine efficiently)].

Although olfactory cues are important controlling stimuli, they are not the only operative environmental stimuli maintaining the habit. The contextual stimuli associated with the area (e.g., substrate texture, visual cues, and location) may also control eliminatory behavior to some extent. It should be remembered that urination is an intrinsically reinforcing activity; that is, the dog obtains some degree of pleasure or relief as the result of eliminating. Environmental cues occurring contiguously with elimination may gradually become discriminative stimuli regulating the emission of the behavior. Consequently, the olfactory cues contained in urine may only represent a part of an overall stimulus situation controlling urinary-marking behavior.

To counteract these environmental influences, new associations must be formed with the soiled area. This task of forming new, noneliminative associations is accomplished in a variety of ways. The simplest method is to feed and water the dog near the marked area (Voith and Borchelt, 1985). Between feedings, the owner can periodically place treats around the previously soiled area as well, so that whenever the dog approaches the location it is likely to find some food. Chew toys can be permanently anchored to the area with a short length of twine. Another useful procedure is to tie the dog off near the area for short periods lasting between 10 and 20 minutes at a time. The area can also be associated with play, massage, and general obedience training. The central purpose of these recommendations is the formation of a new set of associations connected with the area that are incompatible with elimination. As a result of such training, the previously soiled area may come to be identified as a place promising the acquisition food, toys, affection, training, or restraint. Subsequently, the urge to eliminate will be gradually overshadowed by incompatible expectations associated with the area, making the dog less likely to urinate in the area than before. When the owner is away from home, the dog should be confined so that marking is prevented until the problem is under control.

An intact dog presenting with a persistent urine-marking problem is usually referred to a veterinary surgeon for castration. In cases unresponsive to castration and behavior modification efforts, various psychotropic drugs or hormonal therapy may be prescribed by the veterinarian. A common medical intervention involves treatment with synthetic progesterone (Hart and Hart, 1985). Unfortunately, the beneficial effects of progestin therapy often decay once the medication is discontinued. Since the chronic use of progestins may produce a variety of adverse side effects (e.g., mammary hyperplasia, tumors, and diabetes mellitus), its long-term use is not recommended for the control of refractory urine marking.

Elimination in the Owner's Absence

Some otherwise well-house-trained dogs may eliminate in the house only when their owners are away, while they are in another room, or when asleep. Separation anxiety is frequently associated with such elimination problems, especially when "accidents" only occur shortly after the owner leaves the house (McCrave, 1991; Yeon et al., 1999). Dogs whose house soiling is diagnostically linked with separation anxiety must receive appropriate behavior modification to reduce the underlying emotional tensions associated with the loss of bowel and bladder control. Some separation-anxious dogs appear to respond positively to a change of place when left alone. Elimination problems are particularly prevalent in separation-anxious dogs that are confined to an unsocialized part of the home (e.g., the garage or basement). In general, most dogs appear to find confinement in such areas (especially the basement) aversive and prefer to be confined in more socially active parts of the home. In cases where elimination might be attributable to the place of confinement, the dog should be moved to a more socially congenial area, for example, the kitchen or, perhaps, even crated in a bedroom, especially if the dog is accustomed to sleeping there at night.

Although many dogs eliminate (urinate or defecate) in the owner's absence as the result of separation anxiety, some incompletely house-trained dogs may also selectively eliminate only in the owner's absence or do so secretly to avoid punishment while the owner is at home but out of sight. Incompletely house-trained dogs are given remedial training to help improve their habits. Various other causes of elimination problems have been identified and should be considered when performing behavioral assessments of eliminatory complaints (Table 9.2). Such training usually involves a combination of increased vigilance, confinement, and more opportunities to eliminate outdoors. Dogs that are unable to avoid house-soiling behavior during the day may benefit from the assistance of a dog walker who comes in at midday and then gradually delays the visit by an hour or so each day until the dog can accommodate the longer schedule.

The first step in working through elimination problems is to determine the incidence of the unwanted behavior and other pertinent information. Of particular importance in this regard is the schedule of feeding, type of food fed, opportunities to eliminate outdoors (and outcome), and the time/place of accidents occurring in the house. Consequently, careful feeding and elimination records are necessary in order to determine the explicit character of such patterns and how they might be altered to make training efforts more successful (Figure 9.2). Keeping daily records and logging outdoor opportunities often provide unexpected information that may not be obvious through casual observation alone. Such records provide the owner with orderly feedback concerning the dog's elimination behavior and an objective means for assessing its daily progress. Remedial house training can be an extremely frustrating process, and such records objectively show patterns of improvement (or lack thereof) and help to diffuse some of the emotional tensions associated with the process.

Occasionally, in the case of multidog households, it may be difficult to ascertain which dog is responsible for urinating in the owner's absence. Separating the dogs is an expeditious way to identify the dog responsible. However, when separation is not possible or practical, another method may be used to discover the culprit (Karofsy, 1987). The determination can be made by giving the suspected dog a tablet of aspirin before a meal. Within a short period, urination will contain traces of salicylate. When a urine spot is found, it is extracted with a paper towel and ferric chloride is applied to it. If the urine contains the salicylate contaminant, it will turn a burgundy color.

Crate confinement is often recommended to facilitate good eliminatory habits. Although close confinement usually inhibits elimination in most dogs, some dogs may continue to urinate or defecate even when confined to crates. Excluding separation anxiety and health problems [see Reisner (1991)], the most common causes are related to the size of the crate or the amount of time the puppy or dog is required to spend crated between outings. Crates that are too big may not promote fastidiousness, but even if the crate is sufficiently small, some dogs may still eliminate when confined. A contributing cause for this failure is a history of excessively lengthy periods of crate confinement, which exceed the dog's ability to hold. In essence, such confinement presents an uncontrollable situation in which elimination is physiologically unavoidable, perhaps promoting a progressive state of learned helplessness with respect to eliminatory functions. Repetition of such treatment may lead a puppy to simply give up trying to hold urine or feces. Since the effort to hold is useless and progressively uncomfortable, the puppy may respond to the earliest internal signals of need and eliminate withoug trying to hold for long.

Another common difficulty involves dogs that refuse to eliminate on walks or malinger when let outside. This problem is exasperating for the owner, who may walk the dog for long periods, only to return home and discover that the dog quickly runs off to a favorite location in the house to eliminate. Such dogs appear desperate to eliminate but are unable to do so outdoors. Some dogs may have developed overly exclusive substrate or location preferences, whereas others may fail to eliminate outdoors (especially if the owner is nearby) as of the result of a history of excessive punishment,

TABLE 9.2. Common causes of elimination in the owner's absence

Inadequate or inappropriate training
Separation distress
Elimination inhibitions (e.g., fears associated with the outdoors, weather aversions, overly exclusive substrate preferences, and fear of eliminating in the owner's presence)
Irregular scheduling of feedings and outings
Insufficient opportunities to eliminate outdoors and too much freedom to eliminate indoors
Quality or amount of food fed to the dog
Urinary-tract disease (e.g., cystitis)

causing them to generalize the threat of punishment across both indoor and outdoor contexts. These dogs may simply be afraid to eliminate in close proximity with the owner. Giving them more room to move about in a fenced area or exercising them on a long line may help to encourage outdoor elimination, especially if they are prompted with a gentle voice and rewarded with treats for performing. Other dogs may have simply been improperly trained in the first place. To modify these types of problems, the puppy should be taken out at times of greatest need (e.g., in the morning) for brief periods lasting about 1 to 3 minutes (adult dogs, 3 to 5 minutes). A puppy that fails to eliminate is taken back inside and crated or tethered for 10 or 15 minutes and taken outside again. This pattern is repeated until the dog performs outside, whereupon it is reassured with praise and affection. Urination and defecation in such cases can often be facilitated with brief periods of ball play or other vigorous activities that help to promote motility and disinhibition.

Submissive Urination

Submissive urination is most commonly exhibited by young dogs and appears to be more prevalent in female dogs. In most cases, dogs gradually grow out of the problem as urethral sphincter control improves; however, some highly sensitive and excitable dogs may continue to urinate submissively into adulthood, especially if the initial presentation of the problem is mismanaged. Submissive urination is evoked by a variety of social situations: (1) when the puppy or dog is reached for or (2) leaned over (in what might be perceived as a threatening gesture or posture), or (3) during episodes of excited social interaction (e.g., greetings). Submissive urination appears to represent an appeasement display and is often exhibited by a puppy or dog that has been exposed to inappropriate punishment or excessive control efforts; that is, the behavior may be expressed to allay a perceived threat posed by the presence of an overbearing owner, person, or other dog. The behavior may be maintained by negative reinforcement, since it causes the owner to withdraw as urination occurs. Even worse, though, sometimes submissive puppies are punished for urinating, causing them to urinate even more—an action that is also frequently associated with the termination of the owner's punitive efforts. Unfortunately, in such cases, the habit of submissive urination may be strongly reinforced, thus becoming progressively more exaggerated and difficult to resolve. Some cases of submissive urination appear to be linked to punitive interaction early in a puppy's development—for example, during house-training efforts when the puppy is physically punished while eliminating. During such interaction, the puppy may make a rapid transition from functional urination to submissive urination in response to the owner's inappropriate punishment. Consequently, as the owner leans over, reaches for, or touches the puppy, it may respond by urinating.

Although submissive urination is frequently driven by appeasement motivations, it is not always and exclusively due to excessive punitive interaction between the puppy and its owner. Some puppies appear to be predisposed to exhibit this habit spontaneously as the result of excitement and urethral incompetence but usually grow out of it—provided that they are not punished for it.

Submissive urination occurs most commonly during social transitions, that is, during homecomings or while greeting guests. In some cases, the mere sight of a particular family member entering a room may elicit a copious release of urine. The most common posture displayed is an incomplete squat with small amounts of urine being expressed, but some dogs may perform a full squat or actually roll on their side (lateral recumbency) and expose their belly before eliminating. Other signs of submission may also be present (a submissive grin, licking, ears back, or a crouched-down look), but these submissive elements are not always strongly presented.

Submissive urination probably stems from the mother's practice of stimulating reflexive urination in puppies. Fox (1974) has described the relationship between reflexive urination and submissive behavior:

> When two adult dogs or wolves make social contact with each other, one invariably orients

> toward the groin of the other. Groin presentation is usually manifested by the subordinate individual. As a social gesture, it is perhaps analogous to a handshake in man. The next time you see a friendly dog approaching you, notice how he wiggles his head and swings one hip around, presenting the groin. If you touch him in the groin, he will remain completely passive and may even roll over onto one side in complete submission. He may then urinate submissively. Submissive urination is the final clue to the ontogenetic history of this behavior. When wolves, coyotes, and dogs are very young, they are unable to urinate, and the mother reflexively stimulates urination by licking the genitalia. During stimulation the pups remain passive while the mother nuzzles the groin region. Later, of course, the animals are able to control urination voluntarily, but the behavior trait of remaining passive when the groin is touched persists as part of their social repertoire. (42)

In fact, many infantile behaviors involved in nursing, food getting, and elimination appear to be elaborated into mature active and passive submission displays.

Many adult submissive urination problems appear to stem from an emotional etiology. Puppies and dogs with highly excitable temperaments, which exhibit approach-avoidance conflict during greetings, appear to be most prone to exhibit the problem. The treatment of submissive urination begins by carefully identifying eliciting stimuli. Sometimes the reaction to people is specific to one sex, with some dogs urinating only in the presence of males and not females or vice versa. Some dogs have such a low threshold for submissive urination that they respond as soon as the owner or visitor enters their personal space, whereas others may urinate only when being reached for, leaned over, or touched. As just noted, in the case of young puppies (under 16 weeks of age), this is a common and normal habit that usually disappears with maturity. In older puppies and adult dogs, the habit may become more persistent and compulsive, requiring carefully structured behavior-modification efforts to resolve it fully.

Gradual exposure and counterconditioning prove extremely effective in reducing submissive urination. In the typical scenario, the owner is instructed to give the dog a treat on every approach, at first tossing the food on the floor and then gradually requiring the puppy to sit and stay a moment before delivering the reward. Besides eating, the dog can be engaged in other activities such as fetching a toy or, perhaps, taken directly outdoors. This process is facilitated by repeated exposure involving mass trials; that is, by staging repeated contact rituals involving as many as ten approach and withdrawal trials per session, the exposure-counterconditioning process is made more effective. In the beginning, the owner should avoid leaning over or reaching for the puppy or dog. As progress occurs, more obtrusive actions like reaching and leaning over the dog can be attempted, first while the puppy is eating, later while holding a sit-stay, and, finally, under progressively more natural circumstances occurring during actual greetings with family members and guests. In refractory cases of submissive urination, a pharmacological intervention might be considered. Some success has been reported using the alpha-adrenergic agonist phenylpropanolamine—for further information, see Marder (1991) or Voith and Borchelt (1996). The muscles of the urethra are adrenergic, and the drug enhances general tone and control so that, when the dog becomes overly excited or squats, it is less likely to lose control. The drug has potential side effects, such as increased excitability and restlessness. Marder (1991) reported good results using imipramine (Tofranil), a tricyclic antidepressant that also possesses alpha-adrenergic agonist properties.

Defecation Problems

When defecation problems present separately, the usual causes include inadequate or inappropriate house training, separation-related distress, change of diet, or disease conditions affecting the bowel (Reisner, 1991). As already noted in the case of urine-marking behavior, defecation may occur in the house in response to environmental cues that have been associated with defecation in the past. Although dogs do not appear to use feces to mark in the same manner and frequency as

they mark with urine, some do show a tendency to deposit fecal material on vertical objects, suggesting that fecal marking or advertising may occur in some dogs. Few dogs show as much interest in the fecal deposits of other dogs as they exhibit toward urine-marked areas. Anal fluids are secreted into fecal materials as defecation occurs. The exact function of anal secretions is unknown, but they may contain some pheromonal information that is communicated in the feces. In wolves, alphas secrete more anal fluids during defecation than other pack members and tend to concentrate their feces to one area (Asa et al., 1985). One authority has suggested that the dog scratches after defecating in order to spread the scent of feces. This possibility is unlikely, however, since dogs rarely disturb feces with their feet while performing the scratching ritual. Wolves appear to step away from fecal deposits deliberately before scratching (see *Biological and Social Functions of Smell* in Volume 1, Chapter 4).

FLATULENCE

Flatulence is a common complaint. Dogs fed a new diet may develop flatulence, at least until the gut adapts to the change. Some breeds appear to be more prone to the problem than others. For example, brachycephalic breeds frequently have the problem, perhaps because such breeds ingest excessive amounts of air (*aerophagia*) while eating. Aerophagia appears to be a significant cause of flatulence in both dogs and people (Hubbard, 1989). Since dogs ingest more air while eating a liquid diet, changing to a dry kibble may be beneficial in such cases. Another significant cause of flatulence is bacteria fermentation in the lower gut. Undigested food undergoes bacteria fermentation in the colon—a process that increases gas production. Older dogs may be more prone to exhibit flatulence due to an age-related decrease in colonic motility (constipation) and increased fermentation time. Foods that may contribute to flatulence are those containing a high percentage of indigestible fiber (e.g., soybeans). Also, milk may cause flatulence in adult dogs bereft of lactase as the result of the putrefaction of lactose in the gut. In addition to dietary changes, exercise is a useful way to reduce flatulence, because it increases colonic motility and stimulates more bowel movements. Finally, excessive flatulence may indicate the presence of gastrointestinal disease (e.g., malabsorption and exocrine pancreatic insufficiency) and should be brought to the attention of a veterinarian.

GRASS BURN AND URINE

A common complaint of dog owners is the presence of burned spots or dead areas of grass caused by urination. Various putative causes have been suggested, especially the belief that dogs urine is either excessively acidic or alkaline. In fact, the relative acidity or alkalinity of the dog's urine has no effect on its propensity to burn grass. Consequently, it is of little value to feed dogs substances with the intention of reducing the acidity or alkalinity of their urine output. Similarly, putting such materials as gypsum or lime on the grass probably does not help either, at least with respect to neutralizing urine and making it less hazardous to grass. According to Allard (1981), the most likely cause of grass burn is the nitrogenous content of urine. Urine burns grass just as excessive fertilizer would damage it. Since the nitrate content of urine is related to the metabolism of proteins and associated waste products, one potential way to reduce the extent of grass burn is to reduce the intake of dietary protein. In fact, many dogs ingest protein in excess of their activity and physiological needs. A high-quality, reduced-protein food may not only be an effective preventive for lawn burn (especially in the case of resistant grass varieties), but it may also be a healthier diet for inactive house dogs. Also, providing dogs with ample drinking water may produce a beneficial effect by diluting the urinary output. A simple way to prevent grass burn is to walk the dog away from the home property. The dog can learn to treat the yard and garden as extension of the home and keep it clean. If such training is impractical, then daily watering of urine-soaked areas may be helpful. Allard reported that, when urine spots were watered up to 8 hours after elimination, burning was prevented (fescue),

whereas urine left undiluted for 12 hours caused a slight burn, and, after 24 hours, a lack of watering resulted in moderate burning. Some grass varieties are more resistant to urine burn than others. For example, fescue and rye grass were found to be the most resistant to urine burn, whereas Kentucky bluegrass and Fairway crested wheat grass were both very sensitive and burned, even in the presence of highly dilute urine samples.

Cynopraxis

Ultimately, the dog, with its ambiguous roles and cultural values, its constant presence in human experience coupled with its nearness to the feral world, is the alter ego of man himself, a reflection of both human culture and human savagery. Symbolically, the dog is the animal pivot of the human universe, lurking at the threshold between wildness and domestication and all of the valences that these two ideal poles of experience hold. There is much of man in his dogs, much of the dog in us, and behind this much of the wolf in both the dog and man.

DAVID G. WHITE, *Myths of the Dog-Man* (1991)

CYNOPRAXIC COUNSELING

Although descriptive and functional information is useful, its effective and humane implementation depends on properly focusing intervention efforts. For behavioral intervention to work, the *whole picture* must be embraced and kept in focus throughout the assessment and training process. This method is referred to as *cynopraxis.* The ultimate goals of cynopraxic assessment and training are determined by two imperatives: improving the human-dog relationship while raising the dog's quality of life (see *Cynopraxis: Training and the Human-Dog Relationship* in Volume 1, Chapter 10). Analyzing the behavioral complaint into specific functional components (establishing operations, discriminative stimuli, elicited and emitted behavior, and controlling consequences) and the numerous molar relations existing between them is not enough. In addition, cynopraxic counselors must be sensitive to subjective and intuitive considerations associated with the human-dog bond—ultimately the focus of all training and counseling efforts. Behavioral approaches that neglect a dog's physical and psychological needs or fail to appreciate the ultimate value of the human-dog relationship are incomplete, inadequate, and inhumane. Whether adaptive or maladaptive, a dog's behavior is acquired or extinguished by way of interactive exchanges and transactions interfacing or colliding with human needs and expectations. Within the context of a shared home, these combined human-canine needs and expectations are

either mutually satisfied or result in conflict, with an inevitable elevation of interactive tension (anxiety and frustration) ensuing. Excessive anxiety or frustration underlies the development of many behavior problems (see *Learning and Behavioral Disturbances* in Volume 1, Chapter 9). Interactive harmony depends on the identification of a dog's basic needs and developing acceptable and cooperative ways to satisfy them. Dog behavior problems are human-dog problems. Sensitivity in this area makes the difference between mastery and mediocrity in the practice of companion-dog training and behavioral counseling.

Attaching, Bonding, and Relating

A cultural and ethical ambivalence informs the way animals are viewed and treated in our society. Animals are slaughtered for food by some people or honored as symbols of piety and mystical transcendence by others, and at times serving both purposes at once, as in the case of animal sacrifice. Our relationship with dogs is also guided by many conflicted cultural purposes and agendas (see *Theories of Pet Keeping* in Volume 1, Chapter 10). Adding to the confusion is the lack of a consistent terminology for describing the human-dog relationship. Scott (1991) notes that the terms *attachment* and *bond,* for example, are loaded with surplus connotations and often inappropriately used to describe the same phenomenon. However, attachments and bonds are qualitatively different and distinguished on a number of levels. Unlike bonds, attachments can be equally felt toward animate objects (social) and inanimate objects (places and things). Attaching to some object or place does not require mutual exchange between individuals. A bond, however, implies the existence of mutual *ties* between individuals, based on various modes of reciprocal interaction and relating to one another (e.g., transactions and exchanges). Further, bonds are not based entirely on friendly or affiliative transactions and exchanges. In fact, bonds may be strongly influenced by the exchange of aversive transactions and subsequent reconciliations. Bonding may also be enhanced by the exchange of threat and appeasement displays. Finally, exchanges between bonded individuals involve a strong interpretive component based on past experience, mutual expectations, and their changing motivational disposition to interact. These collective attitudes and expectations define the relationship, and the range of possible exchanges and transactions that can take place, between a dog and others with whom it is bonded and interacts.

Cynopraxis and the Human-Dog Bond

The most fundamental unit of cynopraxic analysis is the *human-dog dyad.* A central cynopraxic assumption is that behavioral and emotional problems develop within a system of relations between a family and its dog. People and dogs relate to each other through the exchange of attractive and aversive emotional transactions. These interspecies emotional transactions, the basis of human-dog communication, result in an alteration of both human and canine feeling states, experienced simultaneously inwardly (within the self or organism) and empathically (toward the other). The formation and perpetuation of the human-dog relationship places tremendous demands on a dog's adaptive resources. Under conditions in which these demands exceed a dog's ability to adjust (e.g., under the influence of unpredictable or uncontrollable transactions), the dog may revert to rigid emotional or instinctual systems with which to guide its behavior. Relational conflicts result in varying degrees of anxiety or frustration, with resultant disturbance of behavioral adaptations. Under interactive conditions in which anxiety and frustration levels surpass a dog's ability to cope, it may progressively rely on rigid emotional or species-typical defensive repertoires, thereby side stepping cognitive appraisal of the situation and responding instinctively or dysfunctionally. Consequently, the dog's behavior may become progressively maladaptive, fearful, compulsive, hyperactive, or aggressive.

These functional disturbances of the human-dog relationship take place within the context of a home. Ultimately, the functional significance of a behavior problem is determined by the extent to which it interferes

with a dog's ability to form satisfying relationships with humans and other animals with whom it shares a home. Cynopraxic therapy objectifies the human-dog relationship as the functional unit of behavioral adaptation or maladaptation, set within a context of numerous contributory environmental influences (e.g., nutrition, exercise, and sensory stimulation). These environmental influences composing a dog's *home* collectively define its quality of life. Cynopraxic training aims to enhance the human-dog relationship while simultaneously improving the dog's quality of life. The cynopraxic process is an end in itself, insofar as there are no objectives beyond the attainment of human-dog harmony, mutual appreciation, and well-being.

Behavior Problems and the Family

For purposes of the following discussion, the term *family* refers to any cooperative social group of individuals that lives together and provides for one another's physical, psychological, and emotional needs by forming bonds based on reciprocal transactions and exchanges within the context of a home. The family is not defined or limited in terms of biological relatedness but in terms of emotional and ecological relations sustained within a home. The family may be as simple as a single owner and dog dyad or include complex social relations, as, for example, found in the traditional nuclear family. Whether traditional or nontraditional, many family dynamics and activities are patterned around the dog as an emotional center of gravity.

The mélange of social roles that the dog plays in the family underscores its behavioral adaptability to domestic life. According to Levinson (1969/1997), a dog's role will depend "upon the family's structure, its emotional undercurrents, the emotional and physical strengths and weaknesses of each of its members, and the family's social climate" (122). In most families, the dog is an important object of affection, care, and entertainment—often taken for granted but nonetheless accepted as a beloved member. A dog's presence in the family is harmonious and welcome to the extent that its behavior is well adjusted to the family's needs and expectations. With the advent of a serious behavior problem, however, intense conflicts may compete with or overshadow the more positive aspects of dog ownership. For the family, a problem dog becomes a highly *objectified* presence often precipitating a sense of disequilibrium and familial crisis. As a result, the dog moves out of the fluid background of harmony into a sharp focus of attention, becoming the object of conflict and disruption for family members.

Much of what follows has been adapted from the contextual therapy techniques developed by Ivan Boszormenyi-Nagy (Boszormenyi-Nagy et al., 1991) but remains an eclectic composite containing many influences, especially prominent is the work of Salvador Minuchin (Minuchin and Fishman, 1981) and Murray Bowen (Papero, 1990). The primary emphasis of cynopraxic training is to focus training efforts on the relationship, rather than on simply altering the dog's behavior.

The response of the family to a problem dog varies, depending on several factors. In some dysfunctional family situations, a problem dog may have a disruptive and polarizing influence, with the dog becoming a scapegoat for displaced anger. Rather than searching for legitimate causes and solutions, the dog's unwanted behavior may be used by family members to shame one another. In some cases, a serious behavior problem might actually provide some degree of stability and cooperation within an otherwise conflicted and tenuous family situation. In such cases, the problem dog may give the family a common crisis point, drawing members together in a more or less common cause. Although dysfunctional situations exist (see below), one is much more likely to encounter functional families seeking advice and training for problem dogs. Generally, such families tend to adopt a rational perspective when faced with adversity. In contrast to the arguing and scapegoating that characterize a dysfunctional family, a functional or parenting family is more apt to join together in a cooperative

effort, with each acknowledging their responsibility to contribute to the ultimate solution. Rather than assigning blame, the parenting family is galvanized by a supportive sense of unity and mutual appreciation and respect for one another.

Joining the Family

Although the causes underlying a dog's adjustment problem may implicate the client or another family member, it is important to provide such information without assigning blame. Direct attributions of fault and blame are always polarizing and destructive. Most dog owners seeking help seem to expect some criticism, but framing a behavior problem in terms of fault finding is not the same as exploring potential causes or fact finding. Any potentially critical evaluations should be presented in a manner that is nonaccusatory and followed immediately by positive alternatives. First and foremost, one should avoid direct critical commentary on the family's failings with respect to the dog. Instead of shaming the family, positive resources should be highlighted through merit ascription, recognition of needed abilities, and encouragement. To achieve this end, it is vital that the trainer-counselor *joins* with the family. Minuchin and Fishman (1981) describe the process of joining the family in terms that are highly relevant to the cynopraxic counseling process:

> Joining a family is more an attitude than a technique, and it is the umbrella under which all therapeutic transactions occur. Joining is letting the family know that the therapist understands them and is working with them and for them. . . .. How does a therapist join a family? Like the family members, the therapist is "more human than otherwise," in Harry Stack Sullivan's phrase. Somewhere inside, he has resonating chords that can respond to any human [or animal] frequency. In forming the therapeutic system, aspects of himself that facilitate the building of common ground with the family members will be elicited. And the therapist will deliberately activate self-segments that are congruent with the family. But he will join in a way that leaves him free to jar the family members. He will accommodate to the family, but he will also require the family to accommodate to him. (31–32)

A trainer-counselor who joins the family while blaming and shaming it (regardless of how expert and correct) for the dog's behavior problem may be reflexively held at a distance or expelled psychologically—if not physically! Direct criticism may cause the family members to withdraw into defensiveness and potentially strengthen their own scapegoating tendencies toward one another. The goal is to find and acknowledge as many constructive aspects of the family's interaction with the dog as possible and to build on that foundation. Validation of the family by acknowledging its affirmative value and contribution to the dog's good qualities is beneficial on many levels. The process draws heavily on a spirit of family cooperation and provides an opportunity for members to sacrifice and compromise to attain some greater good for the sake of the group and the dog. It is a process of building on the dog's good behavior rather than a fruitless labor of accusation and penance. Nonjudgmental and fair counselors are better able to establish a working rapport with families and gain their willing and happy collaboration. Furthermore, family members will more likely extend their trust and disclose vital information necessary for an accurate evaluation. By emphasizing the positive aspects of the family dog, an opportunity to strengthen the family's commitment and loyalty to the dog may be garnered, perhaps helping to restore a healthy bond and attachment rather than risking further marginalization of the dog.

In some cases involving severe behavior problems, the relationship between the family and dog may be seriously jeopardized by anxiety, frustration, anger, and resentment. In such cases, it is particularly important to review all of the dog's merits and strong points in order to forge a constructive perspective on the problem situation. For some clients, it may be necessary to underscore the dog's strong points repeatedly and to stress the successes that they have achieved in rearing and training it. Emphasizing what makes the dog special and complimenting these strengths can be very useful. Also, it is of value to acknowledge the client's entitlement to feel angry and resentful but at the same time pointing out to them that rumination

on such feelings is unproductive and may interfere with the dog's progress.

The cynopraxic trainer-counselor's role is first and foremost one of model and leadership. The counselor should exemplify in a direct and personal way how to behave constructively toward the dog, while stressing fairness by not becoming overly partial toward the dog or the family. Although many technical issues are involved in rehabilitating a problem dog, the overall manner or attitude of the counselor is often more influential than any specific recommendation. The trainer models the spirit of the thing in attitude and interaction with both the family and the dog. Essentially, the *work* of trainer-counselors is to resolve *conflict* in the family-dog relationship and restore interactive harmony through training and counseling. From the cynopraxic point of view, the ultimate goal of intervention is not training a dog to sit on command or to stop some unwanted habit but rather to mediate interspecies understanding, behavioral compromise, and interactive harmony—a process that may or may not involve obedience training or behavior-modification efforts.

Fairness and Empathic Appreciation

A central variable informing interactive harmony is a relational ethics based on fairness and empathic appreciation. Boszormenyi-Nagy and colleagues (1991) emphasized the role of fairness in the process of counseling the family: "The balance of fairness among people [and animals] is the most profound and inclusive 'cluster' of relationship phenomena. This is the context to which the term 'contextual therapy' applies" (204). To be effective mediators, cynopraxic trainer-counselors must embody, above all, the virtue of fairness. But, in addition to fairness, trainer-counselors should also express clear and frank opinions, display a friendly attitude toward family members, express and show fondness toward the dog, and impress both family and dog with a clarity of purpose. These are key elements of successful cynopraxic counseling.

Cynopraxic counseling and training aim to guide the client and dog into a more satisfying relationship through enhanced affection, cooperation, and trust. This process often emphasizes the need to establish appropriate boundaries and realistic expectations. These boundaries are established and tempered by empathy, mutual understanding, and leadership. A counselor's role as a mediator often entails helping the client to establish appropriate boundaries and to set limits for the dog. Such structuring of interaction results in the dog developing attentional abilities, impulse control, and better organized and effective goal-directed behavior, while it helps the client to form a clearer set of expectations about the dog's behavior and to feel more in control of things. Although training is objectified in terms of controlled behavior and the formation of definite boundaries and limits, the real focus of training is a higher synthesis and resolution, eventually freeing both human and dog to behave spontaneously and freely with each other. The picture is one of mutual harmony, affection, unity, tranquility, and profound respect—what Fox (1979) has called transpersonal relatedness or an appreciation of the dog without contingency or reference to something else beyond the dog. Transpersonal appreciation involves a direct apprehension of the thing itself or what the poet Rilke has called *inseeing* (see Volume 1, Chapter 10: *Mysticism and the Dog*). Framed as such, the adjustment problem, rather than representing a threat to the family's equilibrium, becomes an opportunity for enhanced cooperation and growth for both the family and the dog.

Multidirected Partiality

As mediators, cynopraxic trainer-counselors should show equal concern for family members and the dog. Such so-called *multidirected partiality* (borrowing Nagy's terminology) embodies the all-important ethical principle of fairness. Effective cynopraxic intervention requires that the trainer-counselor acknowledge the client's expectations without losing sight of the dog's needs and limitations. For example, a client's feelings of anger, betrayal, and distrust are valid emotions to have after being bitten by a beloved dog. But an equally valid set of circumstances may have been responsible for the dog's decision to attack, including past learning experiences, adverse or

inadequate socialization, or abusive behavior by the owner toward the dog in the past. The bite incident was not simply a factual event but a socially and psychologically significant transaction between the owner and dog. To assess the situation properly, the counselor must evaluate the incident both as a factual or behavioral event as well as stress its meaning as a transaction between close social affiliates. This process is facilitated by adopting an attitude of fairness toward both the client and the dog, thereby justly acknowledging their respective contributions to the transaction and assigning mutual responsibility for the consequences stemming from it. This attitude of fairness is not intended to justify the dog's behavior or the client's emotional reaction but to recognize that they exist and require *contextualization* (that is, need to be placed into a perspective based on fairness to both parties). The goal of contextualization is to organize the transaction into a more formal and objective problem picture, rendering it more receptive to intervention and change—not engaging in unproductive judgments, criticisms, and behavioral cul-de-sacs.

Coupled with the mediational importance of exercising fairness is analyzing the problem in terms of bidirectional causality. The purpose of counseling is not to assign blame but to develop a program of positive change in the direction of interactive harmony. *Bidirectional causality* means that both the client and the dog are assigned a fair degree of responsibility for the behavior problem. Neither the client nor the dog is blamed for the development of conflict, but both are held accountable for contributing to its resolution; that is, both the client and the dog must change in order to overcome the problem and to attain a more satisfying relationship. As such, the behavioral complaint is interpreted as a symptom and manifestation of an underlying interspecies conflict and failure to achieve interactive harmony, that is, a satisfying relationship.

PSYCHOLOGICAL FACTORS

The majority of dog owners view the dog as an integral extension of the family unit (Levinson, 1969/1997), exerting many subtle and pronounced influences on the family system. These various effects are bidirectional, with the family also exerting powerful influences on the dog's behavior. In addition to accepting the dog as a family member, most people appear to believe that dogs have minds and the ability to think—a perception that has direct bearing on their beliefs regarding how dogs should be treated (Davis and Cheeke, 1998). With the attribution of awareness, thoughts, and feelings, people are more likely to treat dogs humanely and to appreciate their experience empathically. These various attitudes and perceptions about dogs exert a significant influence on the human-dog relationship.

Influence of Owner Attitudes and Attachment

Precisely identifying, describing, and measuring the influence of owner attitudes on dog behavior has been of interest to researchers. For example, Serpell (1996) has reported suggestive evidence indicating that the owner's degree of attachment for a dog has a direct bearing on how satisfied or dissatisfied the person will be with the dog's behavior. A family feeling a strong attachment and affection for a dog tends to be more accepting and tolerant of its behavior. The power of attachment can be quite extraordinary in regards to how behavior is judged. Voith (1984), for instance, recounts an interview with a woman whose baby had been tragically killed by her dog. Surprisingly, she spoke lovingly of the dog and attributed "accidental" causes to the child's death, refusing to blame the dog and hold it accountable for its actions. The grieving woman greatly lamented the loss of the dog and had great difficulty reconciling her affectionate feelings toward the dog with the fact that it had, after all, killed her baby.

Owner Mental States and Behavior Problems

Although the supporting evidence is sparse and contradictory, owner and family attitudes and mental health appear to exercise a significant influence on a dog's behavior. How this occurs remains subject to considerable debate and controversy. Certainly, the manner in

which the owner applies behavior-controlling events (e.g., rewards and punishments) will directly affect a dog's behavior through learning and training. Owners, as the result of mental illness or other causes (e.g., alcoholism), who are unable to interact with a dog in a consistent manner, would naturally exert a disorganizing influence on its behavior. Further, just as attachment levels appear to affect an owner's perception of a dog's behavior, his or her attitude and mental state may also have a direct bearing on the dog's emotional state. Speck (1965), a psychiatrist, reported observing a direct relationship between severe mental illness and a contagion effect on animals living in the same household. In one case report, he described how the agoraphobic symptoms of a mother, father, and schizophrenic daughter were mirrored in a dog and cat that also refused to leave the house. In another report, Speck (1964) noted that, when performing in-home psychiatric counseling with families in which dogs or other companion animals were present, the animals were apt to reflect the family's general attitude toward him. He claims to have learned to predict a friendly, angry, or indifferent session by the way that he was greeted by resident cats and dogs. Further, he reports making a "repeated observation" (152) that in disturbed families the dog may become ill as a result and, if harmony is not restored, may actually die.

These sorts of presumably strong social influences exerted by an owner or family on a dog have not been widely confirmed by practitioners working with problem dogs. Although most counselors and trainers would agree that an owner's attitude or mental state should exert some influence, what the influence might be has not been fully worked out. Some evidence has appeared in the literature in support of such effects, however. For example, O'Farrell (1995) notes that owners suffering from mental disturbances tend to project undesirable qualities and traits onto their dogs more frequently than do owners without such mental problems. Neurotic individuals also tend to report more problematic behavior in their companion dogs. In a relevant study, O'Farrell (1997) was not able to detect a causal relationship between the owners' anxiety levels and the etiology or maintenance of common phobias in dogs (e.g., fear of thunder)—a contagion previously believed to exert a powerful influence on the development of fears (Beaver, 1982). Although not a causal factor, owner anxiety levels do appear to affect how troubling or disturbing the dog's fearful behavior is for the owner. Finally, Dodman and colleagues (1996) performed a small study (N = 10) to assess, among other things, the effects of owner personality traits on the expression and treatment of dominance-related aggression. They did not detect any significant personality-type differences between owners of dominant-aggressive dogs and a control group composed of 10 owners of nonaggressive dogs. The researchers did find, however, that *thinking-type* owners were more likely than *feeling-type* owners to achieve 50% or better improvement in their dogs as the result of implementing a nonconfrontational treatment program.

Triangular Relations

Nearly all families regard their dogs as full members (Cain, 1983; Voith et al., 1992), with some dogs enjoying a privileged status and receiving extraordinary care and affection, whereas others are marginalized and pushed outside of the family's inner circle. Feelings of attachment for the dog often widely differ between family members, with disagreements about the significance or acceptability of the dog's behavior being fairly common. The quality of attachment between family members and the dog may also undergo degradation or disturbance as the result of a behavior problem. Another common source of disturbance involves various patterns of triangulation. Triangles and triangular relations develop in situations where a third party is incorporated into a dyad relationship to deflect intense emotional states (e.g., anxiety and anger) and to secure stability (Papero, 1990). The family dog may be triangulated as an alternative object for feelings of affection, anxiety, or anger arising between family members. As a consequence of such triangular relations, Schurr-Stawasz (1997) suggests that the dog may be variously viewed by family members as a "peacemaker, tension-breaker, or scapegoat" (354). She describes an interesting triangle involving a

dog that became aggressive whenever a teenage boy was yelled at by his mother. Interestingly, however, the dog refrained from barking when the boy initiated the yelling. The boy interpreted the dog's selective aggressive behavior as evidence of its having taken sides with him against the mother.

Triangulated relations may simultaneously enhance attachment and affection levels toward the dog by some family members while reducing these measures of affiliation felt by other members of the family for the dog. In the aforementioned case, the boy might feel closer to the dog when arguing with his mother, while she may feel increasingly irritable and angry at the dog at such times. Fogle (1983) describes an interesting triangle involving a husband, wife, and pet parakeet. Upon returning home from work, the husband would habitually say hello to the parakeet before acknowledging his wife. As a result, the wife gradually developed a "death wish" for the bird:

> Their relationship and attitude to the bird was as clear an indication as any that the marriage was going through a rocky stage (which, incidentally, they were acute enough to observe, strong enough to accept, and willing enough to overcome). The parakeet was a focus for their problems and for a time even made the situation worse. (146)

Given the general effects of attachment levels on a family's perception of the dog's behavior, the disruptive implications of adverse triangles should be apparent and addressed as part of the counseling process. As the result of these and various other considerations, it is of utmost importance that behavioral interventions include the family as a group whenever possible. This is particularly important in the case of interventions involving serious behavior problems, where numerous lifestyle changes and commitments of time might be required of family members. This process can be highly disruptive and frustrating for everyone closely involved with the dog. Consequently, for effective intervention to occur, trainer-counselors must appreciate the influence of family dynamics on a dog's behavior and be sensitive to a family's needs.

Attributional Styles

A potentially valuable approach for understanding the influence of owner attitudes on dog behavior and adjustment problems is provided by analyzing the various ways or *styles* with which the owner interprets his or her influence over significant events [see Davison and Neale (1994)]. As discussed in Volume 1 (see Chapter 9: *Locus of control and Self-efficacy*), attitudes and biases exert a significant influence on learning and personal efficacy beliefs. Believing that control over events is within one's personal ability (*internal* locus) produces significantly different expectancies regarding one's efforts. For example, if one believed that the significant causes of some event were located outside of one's reach and influence (*external* locus), one probably would quickly lose hope and despair of influencing those particular events through personal effort. Attributional styles are not only influenced by locus of control tendencies but are also affected by general attributional characteristics associated with the identified causes, especially their relative generality (*global-specific* continuum) and persistence (*stable-unstable* continuum). Negative global and stable attributions in conjunction with a history of failure in coping with a dog's behavior may cause its owner to experience a high degree of anxiety and helplessness, thereby disrupting his or her ability to address the problem in a constructive or solution-oriented manner.

The extent and duration of a client's frustration or sense of *helplessness* appear to be strongly correlated with the character of internal and external attributions expressed by the client. For example, owners expressing the belief that they lack the necessary emotional qualities (*internal global* attributions) or physical abilities (*internal stable* attributions) needed to control their dog effectively may be expected to harbor a long-term sense of helplessness with regard to their ability to resolve a behavior problem that requires the *internal* attributes that they believe they lack. In addition to promoting a sense of helplessness, negative global or stable internal attributions may also adversely affect an owner's self-esteem, especially if the lacking quality or

ability is perceived as a personal shortcoming. On the other hand, owners who express (or hear) global and stable external attributions, such as biological predispositions (external global attributions) or lasting behavioral deficits resulting from adverse epigenetic events (external stable attributions), may come to believe that their dog's behavior is not likely to change in response to personal efforts, since it is influenced by external causes beyond their control.

To be maximally effective, trainer-counselors must, first of all, help owners to identify faulty or destructive internal or external attributions that block effective intervention. Secondly, counselors should provide owners with more constructive ways with which to interpret and understand the dog's behavior, such as isolating and describing objective causes that can then be addressed through appropriate training and behavior modification. This is especially pertinent in cases involving global and stable internal attributions that compromise an owner's self-esteem.

Enabling and Facilitating

Negative or pessimistic attributional styles appear to express themselves in a variety of dysfunctional ways. Paradoxically, for example, unwanted behavior is often inadvertently perpetuated by owners. Such owners can be divided into two types: *enablers* and *facilitators.* Enablers are distinguished from facilitators by the degree of awareness the enablers possess regarding their contribution to the problem situation. Facilitators are usually much more consciously aware of their active role in the development and perpetuation of the dog's unwanted behavior than are enablers. Further, facilitators are more willing to view the dog's behavior problem in terms of externally objective and controllable factors. Enablers, on the other hand, are often unconscious or unaware of the active role they play in the maintenance of the dog's problem.

Enabling owners are among the most difficult to counsel. They are usually congenial, ostensibly open-minded, and sensitive, but they are often very inhibited with regard to discipline and often lack healthy assertive skills—characteristics that may reflect compromised self-esteem. In matters of professional careers, however, they are frequently very competent in controlling the people with whom they interact in supervisory capacities. I recall a psychologist who worked on a daily basis with violent offenders with great effectiveness as a prison psychotherapist, but who was entirely victimized by her Lhasa apso. It is very difficult to make enabling owners fully aware of their *actual* contribution or to explain how their behavior is impacting on the dog's behavior. They are typically defensive and inclined to place the locus of the dog's problem on the level of some personal shortcoming or failing, underscoring the role of personal self-esteem in such cases. Unfortunately, such internalization may serve to place the problem outside of objective control and change. The distinctive marks of enablers are denial, victimization, and helplessness.

Denial

Denial plays a very important role in such cases; in fact, denial is a distinctive feature of enablers. Habitual denial gives a dog's problem autonomy, placing it outside the reach of rational control. Instead of approaching the problem systematically, an unhealthy atmosphere of shame, resentment, anger, defeat, and hopelessness may begin to hang gloomily over the relationship. These emotions effectively disable an owner and preclude effective action. Denial takes many forms from simply refusing to recognize the existence of the problem to articulating complex pseudoexplanations and rationalizations to account for the dog's behavior. When the misbehavior happens to occur in public, the owner's positive self-image may be threatened or damaged, causing him or her to engage in various "excusing tactics" aimed at making amends for the dog's behavior while at the same time striving to restore their good public image (Sanders, 1999). When discussing their dog's behavior, such clients tend to disclose large amounts of irrelevant information, including detailed explanations, prefaces, justifying accounts, mitigating interpretations, spurious

anthropomorphic causes, and tangential external attributes based on physical ailments or maturity issues. The entire interview may be seeped in a normative language, serving to justify the dog's behavior and making excuses for it, rather than attempting to identify and assess functional causes objectively. Under the influence of denial, the problem is further cultivated and simultaneously pushed out of the reach of effective intervention.

Sabotage

Cynopraxic counselors are not only faced with the very delicate job of objectifying a dog's behavior but also with overcoming a client's active and, more often than not, passive resistance and sense of helplessness. This resistance is not always conscious. In fact, most clients appear very frustrated with themselves for not being able to come to grips with their dog's behavior. Besides lacking the necessary assertive skills needed for effective training and the draining influence of passive resistance, training efforts are often sabotaged. Sabotage takes place on two levels. The dog's behavior problem may serve some dysfunctional purpose within the overall family system; for example, the dog may be triangulated within a family suffering general conflict and disturbance. In some unfortunate situations, the dog may represent the most stable and unifying point of interaction in the family. Occasionally, mental illness or alcoholism exists, and the dog's behavior problems are used by family members as a vehicle to act out or as a weapon directed against each other. Under such conditions, the dog is very likely to fall victim to abuse stemming from unpredictable and alternating mood swings involving affectionate and violent displays.

More often than not, sabotage is the result of enabling and denial. As already noted, enablers are not always aware of their behavior and how it can affect a dog. This is an outcome of the sometimes fanciful and unrealistic picture that clients can paint of dogs. Such owners may maintain and protect this mental escape by behaving in a manner consistent with its underlying presumptions. This state of affairs generally involves substantial emotional and psychological armoring against criticism—armor as amorphous and fluid as shifting sands, yet as hard and impenetrable as stone. In some cases where serious problems develop, instead of giving up the fantasy and emotional satisfaction derived from the myth, such owners simply give up the dog. This situation is reminiscent of Lorenz's (1955) observations with regard to many dog owners whose insensitivity and selfishness are grossly apparent:

> If I question a man who has just been boasting of the prowess and other wonderful properties of one of his dogs, I always ask him whether he has still got the animal. The answer, then, is all too often. . . "No, I had to get rid of him—I moved to another town—or into a smaller house—I got another job and it was awkward for me to keep a dog." (148)

Besides pervasive helplessness, one of the most striking features of enmeshed owners is a pronounced selfishness that weaves itself through the fabric of their relationship with the dog. Selfishness stands out like Pinocchio's nose on a facade of childlike devotion and love toward the dog. It is very interesting to note how much enabling owners complain of the sacrifices they make for their ungrateful canine companions.

Whenever it occurs, denial reflexively results in sabotage. If owners believe that the dog's elimination problem is calculated to make them feel upset or to keep them from going out or to prevent them from inviting a friend to visit, they are not likely to put sufficient effort into proper house-training measures to correct the problem, since they do not really believe that the dog has a house-training problem based on those sorts of causes. If they believe that the dog is compelled by a history of previous abuse to act out aggressively toward guests, they are unlikely to carry out the necessary corrective measures to modify the unwanted behavior. The failure of many training efforts is a direct result of denial and sabotage.

Futurizing

Finally, most people have a strong tendency to procrastinate—to put things off that make them feel uncomfortable. Some people,

though, engage in an *unconscious* form of putting-off behavior that operates in combination with denial and sabotage. This form of denial is referred to as *futurizing*. A common form of futurizing occurs when puppy owners put off training, hoping that the dog will grow out of its misbehavior without their support and guidance. More problematic forms of futurizing occur when owners delay seeking help for a behavior problem and instead allow it to develop into a more unmanageable form, ostensibly believing that it will magically disappear. Futurizing as a form of denial is strongly influenced by collateral anxiety or a fear of failure associated with the process of coming to grips with the problem. Sometimes the issues surrounding the problem may simply be too painful for clients to face, and consequently seeking help is indefinitely put off.

Psychodynamic Factors

The vast majority of clients with problem dogs possess constructive attitudes toward their dog's behavior problem. Occasionally, however, clients will have special needs that require additional understanding and patience. This is a complicated area of counseling that is highly speculative and influenced by psychodynamic concepts that are controversial among behaviorist practitioners. In those relatively rare cases where a dog behavior problem occurs in conjunction with a human psychiatric disorder or substance-abuse problem, counselors are strongly advised to consult with appropriate professionals familiar with such matters.

Dogs are sometimes conceptualized by owners as idealized children or *transitional objects.* Unfortunately, necessary boundaries and reasonable expectations are often suspended when dogs are thought of in such ways. As a result, an owner may lose sight of the dog as a dog, concealed as it is under a projected mask composed of an awkward and ill-balanced concatenation of fantasy and reality. This process of projective idealization incorporates dogs as transitional objects, similar in psychological function to stuffed bears for children. A child treats a stuffed animal as though it were an animated object with feelings and cognitions but realizing all the while that the toy is neither alive nor sentient. In many ways, dogs are sometimes treated as such toys, with the very different and problematic difference that they are both very much alive and sentient:

> That dogs serve as "transitional objects," in a fashion similar to teddy bears, security blankets, and any one of a number of the soft talismen that youngsters carry around to provide comfort when they have been disappointed or are feeling lonely, has been observed by some psychologists and psychiatrists. They do not reconcile that, however, with their equal certainty that dogs represent surrogate children. Although they do not say so, perhaps what they mean is that babying encompasses being babied in that people are giving what they want to get, or that in the minds of infants they and their mother are felt to be one. But there is an important difference between teddy bears and dogs. Dogs are not inanimate but living creatures with whom we have distinctive relationships as much shaped by their species characteristics and individual makeup as by ours. The teddy bear's responses are as we imagine them to be, but Rover's are really those of a dog. (Perin, 1981:81–82)

The result is that many psychological defenses like projection, transference, and splitting may be actively incorporated into the human-dog relationship, which may consequently become progressively fantastical and dysfunctional (Heiman, 1956). The resulting sense of closeness and affiliation may be intensely satisfying for owners, but fraught with many dangers for their dogs. Ensuing magical thought patterns may blur or entirely overshadow an owner's ability to assess and evaluate their dog's behavior objectively (see *Psychoanalysis and the Human-Dog Bond* in Volume 1, Chapter 10).

Such owners may appeal to strange anthropomorphic explanations and justifications for their dog's shortcomings. When problems arise, which they frequently do, the owners often resort to enabling denial and sabotage. They are also inclined to describe their dog's misbehavior in terms of self-centered concerns, especially the emotional pain it causes them. When a dog's behavior falls short of expectations (which are usually very idealized and unrealistic), such owners may feel personally

affronted, deeply let down, often lamenting their attachment and love for the unappreciative dog, and, finally, express painful feelings of victimization and helplessness—the ultimate risks of dysfunctional emotional and psychological exploitation of dogs as attachment objects [see Rynearson (1978)].

SOCIAL PLACEBOS

Some authorities have speculated that a significant factor contributing to the effectiveness of holistic therapy procedures (e.g., homeopathy, acupuncture, and therapeutic massage) results from a special placebo effect or *effect of person* on receptive patients (Rosenthal, 1981). Such therapies share a number of characteristic features. Typically, holistic treatments are rather time intensive, requiring sustained doctor-patient interaction. During treatment sessions, patients are subjected to repeated positive suggestions about the effectiveness of treatment, frequent verbal and nonverbal expressions of care and interest, gentle and reassuring touch during examination, and positive predictions about recovery. The result of such positive interaction and prognostication is an *interpersonal expectancy effect* (IEE) or social placebo. Placebo effects appear to exert a significant impact on the efficacy of medications used to control dog behavior problems (White et al., 1999), perhaps as the result of owner perceptions of the dog's problem, as a result of changes in the interaction between the owner and the dog or both. Some recent research suggests that placebo effects may represent as much as 75% of the beneficial effects of many common antidepressants used to control human depression (Enserink, 1999). Unfortunately, most of the putative benefits of psychotropic drugs used to control dog behavior problems have been obtained as the result of clinical impressions and unblinded studies. Recently, efforts have been made to correct this shortcoming with the appearance of appropriately controlled and blinded studies to assess the *real* effects of these various medications objectively.

Rosenthal (1981) notes that opinions and nonverbally expressed attitudes (self-fulfilling prophecies) have a profound negative or positive effect on health, learning, and therapy. For instance, patients told by an optimistic physician that they are going to recover from a disease as the result of taking some particular medication seem to do better than those told not to expect very much from the medicine. The tendency for such self-fulfilling prophecies to occur have been scientifically evaluated under a variety of controlled conditions. Placebo effects strongly influence experimental results in cases where the study design does not control against experimenter bias. For example, researchers biased by false information about their subjects tend to confirm the expectations in their data, leading to the necessity and use of experimental safeguards like double-blind procedures. Other influences of IEE have also been identified. Teachers misled to believe that certain students possess gifted learning abilities (even though they do not) unconsciously conspire to make the child's scholastic achievement measure up appropriately to those expectations. IEEs are mediated by many interpersonal devices, including indirect ones like tone of voice and body language. For example, children who have been falsely assigned special abilities are often given more opportunities for success and receive more affectionate support for their successes—they are treated as special people and begin to respond as such.

Skillful cynopraxic counselors utilize social placebos and engender positive expectancies in the client-family toward the problem dog. Emphasizing the dog's strong points, placing focus on positive resources, and forming an optimistic perspective on the behavior problem can exercise a very powerful and beneficial influence over the outcome of behavioral training. At the very least, establishing a positive relationship with the client and family will make it more likely that they will accept instructions and carry out training recommendations. On the other hand, a trainer who fails to *join* (borrowing Minuchin's term) the family, or is actively rejected by it as the result of negative interaction or unwelcome criticism, will not likely engender confidence or willing cooperation. Placing the training process on a positive, optimistic level, while applying effective behavioral strategies and maintaining an objective assessment of progress, is an art that cynopraxic counselors must master to be effective.

The Cynopraxic Trainer's Attitude

In addition to embracing scientific knowledge, cynopraxic trainer-counselors acknowledge the value of play, esthetic appreciation, emotional empathy, compassion, and ethical constraint. The cynopraxic trainer's attitude is distinguished by four overlapping characteristics and qualities that mediate connectedness, facilitate the bonding process, and support behavioral healing: composure, sincerity of purpose, presence, and playfulness. *Attitude* refers to a trainer-counselor's mental, emotional, and physical orientation toward the client-owner and the dog. Skilled and effective trainers appear elegant and efficient, cheerful, and gentle, even when setting the most definitive boundaries and limits on a dog's behavior. A cynopraxic trainer's movements are coordinated to *connect* optimally with a dog's behavior in a spirit of harmonious cooperation. Mental and physical composure and consistency make such connectedness possible. Composed trainers show a keen awareness and sensitivity to detail and the ability to focus attention in such a way that training activities possess a quiet presence and precision, without evidence of stifling hesitation, indecision, or doubt. Composure of the *mind and heart* is facilitated by formal and disciplined training activities and humane education in the arts and philosophy. Perhaps the most distinguishing quality of a cynopraxic trainer's character is spontaneity—the cumulative outcome of self-discipline and acquired skills, combined with a beginner's spirit of humility, wonder, and love for dogs.

Sincerity of purpose is closely related and dependent on composure and is the hallmark of a good trainer. *Sincerity* refers to a state of transparent honesty and an ability to express precisely and immediately what is appropriate and fair in response to a dog's behavior. All training interaction with the dog is carried out in a manner that is ever consistent with what the trainer believes necessary to actualize the dog's potential. Josephine Rine (1936) nicely described the value of sincerity of purpose in dog training:

> Look right at the dog as you talk to him, and endeavor to make your tone of voice carry out your meaning no less than your words. The dog is very sensitive to his master's facial expression so be consistent and look pleased or severe as the occasion demands and the spoken words imply. In other words, be sincere with your dog if you would have him retain his confidence in you. Don't expect too much, but on the other hand, don't demand one thing and accept another. (199)

Through sincerity, a direct and reflexive connection is established between what a trainer believes to be in a dog's best interest and what the trainer does. As a result, the trainer becomes a source of consistent, predictable, and controllable interaction, providing a vital foundation for the nurturance of affection, communication, and trust.

Presence is a necessary corollary of composure and sincerity, insofar as a trainer is able to maintain a constructive working relation and *connection* with a dog over time. Dogs live in the moment and, if trainers wish to live and work in close harmony with dogs, they must learn to relate to dogs in terms of a moment-to-moment connection. On a most fundamental level, orientating and concentrating on the present moment is a necessary stance for observing a dog's behavior and properly timing the delivery of training events. All training activities take place in the present tense, and a vital connection between a human and a dog is formed by collecting and focusing on the present. People and dogs connect and bond in the moment, with every simple joy and transformation taking place within the opening and closing of a perpetual threshold between the past and the future. Within the moment, a shared "now" is revealed around which we choose to stay together, cooperate, and live. A dog's experience is in the present moment, with the past and future having little significance, except insofar as they possess meaning for the present.

This present-tense orientation is most effectively organized and mediated through cynopraxic training and play. Training gradually attunes human and dog awareness to the same moment of shared exchange and cooperation or interactive harmony. Remaining true to the moment is most harmoniously achieved through the agency of play. The German

philosopher Friedrich Schiller (1795/1981) observes that play is an essential aspect of our humanity, boldly stating that "Man plays only when he is in a full sense of the word a man, and *he is only wholly a Man when he is playing*" (80). According to Schiller, an artist's ability to make art and our ability to appreciate it as a thing of *beauty* are fully dependent on our play impulse. Similarly, the ability to train dogs is an art that depends on a trainer's ability to play and a dog's ability to play in turn. Where there is no play, there is no relationship or meaning. Play opens the portals of affection and trust between humans and dogs. *Humane* dog training is playing with a purpose, or as Heine Hediger (1955/1968) correctly surmised: "Good training is disciplined play" (139). Cynopraxic trainers embody a playful spirit and value above all else the dog's gift of play.

Index

Handbook of Applied Dog Behavior and Training, Volume Two: Etiology and Assessment of Behavior Problems is a definitive handbook for dog trainers, behaviorists, breeders, veterinarians, and others who have a serious interest in dog behavior and training. Readers will benefit from the author's twenty-five years of study and experience with dogs as a behavioral consultant and trainer.

The vast majority of dogs exhibit at least one undesirable habit. Most of these problems are responsive to remedial training and brief counseling. However, some behavior problems are the result of a more complex etiology involving adverse emotional influences, cognitive disturbances, or pervasive behavioral disorganization. If not properly identified and treated, such problems may lead to the dog being removed from the home or euthanized.

Volume 2 of *Handbook of Applied Dog Behavior and Training* explores the collective causes underlying the development of serious adjustment problems in dogs. Coupled with Volume 1: *Adaptation and Learning*, Volume 2 provides a comprehensive theoretical and practical framework for understanding the development and treatment of behavior problems.

The focus of Volume 2 is to present and evaluate the relevant applied and scientific literature, with the goals of clarifying what is known about the etiology of dog behavior problems and highlighting what yet remains to be learned. In addition, the author introduces several alternative ways for analyzing and understanding the etiology of behavior problems. Topics covered in depth include:

- History of applied dog behavior
- Behavioral etiology and assessment
- Fear, anxiety, and phobias
- Separation-related problems
- Compulsive behavior problems
- Hyperactivity
- Dominance, territorial, and fear-related aggression
- Appetitive and elimination problems

This volume is an authoritative and thoroughly referenced text that is written in a highly readable and enjoyable style. There are no other applied dog behavior texts of comparable quality and thoroughness available.

Steven R. Lindsay, M.A., is a dog behavior consultant and trainer living in Philadelphia, Pennsylvania. He provides a variety of training and counseling services designed to enhance the human-dog bond and improve dogs' quality of life. In addition to his long career working with companion dogs, Mr. Lindsay previously evaluated and trained highly skilled military working dogs.

Preface

A unifying focus of the *Handbook of Applied Dog Behavior and Training* has been to collect and organize a coherent and integrated body of scientific knowledge with practical and theoretical relevance for understanding and controlling dog behavior—especially problem behavior. The information has been collected from diverse areas of scientific research, including canine evolution and domestication, ethology, behavioral ontogeny, neurobiology, cognition and emotion, and learning. The process of assembling and organizing the information contained in this work bears a resemblance to what E. O. Wilson (1998) has referred to as *consilience*, that is, an inventive linking together of facts and theory from different scientific disciplines to produce a framework of explanation and novel hypotheses. This eclectic process of tying together data-based theoretical accounts and experimental findings from diverse fields not only reveals a significant interdisciplinary order and unity between them, it also produces an astonishing diversity of new ideas and possibilities for taking a fresh look at the organization and disorganization of dog behavior.

The selection of topics covered in Volume 3, *Procedures and Protocols*, has been largely based on criteria of practical relevance and value for dog behavior specialists providing professional behavior therapy, counseling, and training services. Various themes introduced in Volumes 1 and 2 are revisited and expanded upon, especially with regard to significant social, biological, and behavioral influences that impact the etiology of behavior problems and their treatment. Although Volume 3 can stand alone for reference purposes, fully appreciating the finer details and distinctions referred to in the text requires that readers be familiar with the contents of Volumes 1 and 2. There is extensive cross-referencing to these previous volumes, especially when a topic covered requires additional background information or explanation not reviewed in the discussion. Ethological observations, relevant behavioral and neurobiological research, and dog behavior clinical findings are reviewed and critiqued, while various protocols, procedures and techniques are introduced and explained in detail.

Advances in neurobiology, cognitive neuroscience, and psychobiology are revolutionizing our understanding of the neural substrates mediating emotion, cognition, executive functions (attention and impulse control), and learning. In addition to studying normal function and development, brain scientists have accumulated a growing and impressive body of scientific information concerning the organic and stress-related causes of abnormal behavior. Of special interest are experimental efforts under way to tease out and trace the neural substrates mediating expressive emotional behavior and learning. According to a prominent psychobiological theory of emotion postulated by Panksepp (1998), emotional command systems interact in biologically prepared ways to modulate (inhibit or excite) and shape the expression of motivated behavior. Behavioral disturbances may result from adverse learning or traumatic events disrupting the equilibrium of emotional systems—a theory possessing significant practical value for understanding and treating a variety of dog behavior problems. Panksepp's quadrant of emotional command systems nicely dovetails with the primary drives traditionally ascribed to dog behavior. Another exciting area of basic neurobiological research that is relevant for applied dog behaviorists and trainers involves work that is tracing the neural basis of reward. For example, strong data suggest that dopaminergic reward circuits are activated or depressed in accordance with the

occurrence of positive and negative predictions errors—findings that have far-reaching theoretical and practical implications. The neurobehavioral investigation of expectancy, comparator mechanisms, and prediction error is poised to revolutionize our understanding of learning and the significance of reward and punishment. Prediction and control expectancies, calibrated establishing operations, emotional command systems, and the prediction-error hypothesis figure prominently in cynopraxic training theory.

Vulnerability to emotional distress and stress appears to play a significant predisposing role in the etiology of many dog behavior problems. The ability of dogs to cope with stressful situations is influenced significantly by the type and degree of stress that they are exposed to in early development. Although some limited exposure to stress is beneficial, inappropriate stress and traumatic fear conditioning may produce a lasting adverse effect on the way dogs cope with stressful situations in adulthood. The organization and functional integrity of the brain are strongly influenced by prenatal and early postnatal stress, perhaps predisposing dogs to develop a variety of stress-related behavior problems and disorders. A very active and productive area of brain research has been dedicated to exploring the effects of adverse postnatal stress on the developing brain and behavior. Some of this research has been reviewed in the context of potential factors that predispose affected dogs to develop aggression and separation-related problems. In addition, brain scientists are closing in on the genes, receptors, circuits, and complex matrix of biochemical pathways mediating the learning and expression of emotional behaviors. This research suggests that highly effective and precisely targeted medications might be available in the not-too-distant future for controlling fear-related problems and aggression that currently remain refractory to conventional treatment. Finally, neurobiology has considerable value for identifying putative organic causes of behavioral disorder and the probable mechanisms mediating pharmacological benefits, which is information of considerable value to veterinarians requiring coherent rationales for prescribing psychotropic medications to manage behavior problems. Knowledge of neurobiology and behavioral pharmacology offers nonmedical behavior modifiers insight into the close link between brain function, emotion, and behavior, and provides an improved appreciation of the use of drug therapy in the treatment of behavior problems.

What a dog does, its propensity to learn, the range of what it learns, and the way it goes about learning it are preemptively influenced by biological constraints. These phylogenetic predispositions include both evolutionary adaptations of an ancient origin as well as more recent changes wrought by domestication and selective breeding. Although heredity exerts a powerful effect, the social and physical environment plays a decisive role in the way these biological propensities are expressed in a dog's behavioral phenotype. From conception to senescence, biobehavioral ontogeny is in a continuous process of change and adaptation, with each stage in a dog's development affecting subsequent phenotypic physical and behavioral characteristics and organization (epigenesis). Whereas normal and protective environments nurture adaptive behavior, abnormal and distressing environments facilitate the elaboration of various emotional and behavioral disturbances increasing a dog's vulnerability to serious adjustment problems. In addition to the disturbing effects of adverse early experiences (e.g., prenatal and neonatal stress, early abuse and trauma, and social deprivation), a wide range of disorganizing emotional and behavioral effects are mediated by stressful or neurotogenic environments possessing insufficient order and regularity to promote social competence and adaptive success.

Environmental pressures shape both phylogenetic and ontogenetic adaptations. Dogs are compelled by an ever-present array of internal and external environmental pressures to adjust in various ways. In addition to an assortment of relatively rigid adjustment mechanisms (e.g., reflexes and modal action patterns), dogs are biologically equipped to adjust to environmental pressures by means of behavioral changes organized by learning. Dogs possess sophisticated cognitive, instrumental,

and associative learning abilities that enable them to cope with and adapt to complex and variable environmental circumstances. These abilities enable dogs to find and exploit necessary resources (comfort seeking) and to detect, escape, or avoid environmental hazards in the process of doing so (safety seeking). Competent instrumental control over significant aversive and attractive events is only possible to the extent that a dog is able to anticipate and prepare for their occurrence in advance, which requires that the environment possess a certain degree of regularity and constancy with respect to such events and that the dog possess the ability to codify the benefits of experience into a useful and accessible form. The predictive information needed is obtained by means of classical conditioning, whereby contexts and incidental stimuli that regularly anticipate significant events are associatively linked, thereby preparing the dog emotionally and behaviorally to respond effectively. Learning of this sort provides a major organizing or disorganizing influence via the formation of prediction expectancies and preparatory appetitive and emotional establishing operations. Behavior operating under excessively disordered circumstances tends to produce varying levels of conflict and stress (anxiety and frustration), attentional strain and disturbance, impulse-control deficits, insecurity, emotional reactivity and panic, and behavioral incompetence—sequelae often associated with common dog behavior problems.

Just as evolution depends on an organism's capacity to maintain stability while changing, the optimization of prediction-control efforts depends on a balance between necessity and uncertainty. Whereas evolutionary advances are the results of life and death experiments etched into a species' genome and transmitted by genetically related individuals to progeny, behavioral adaptation proceeds in accord with interactive experiments consisting of social exchanges and transactions that transmit a collective culture, whereby culturally related individuals and their progeny are able to coexist in relative harmony and security (comfort and safety). Although the attainment of enhanced prediction and control over environmental events is a significant adaptive priority of organized behavior, learning does not proceed by the confirmation of prediction and control expectancies alone, but depends on adjustments resulting from the detection of prediction errors. Logically speaking, well-predicted and well-controlled events routinely produced by the dog do not require that it learn anything else about them beyond what it already knows, at least so long as the situation remains the same. The occurrence of such anticipated outcomes may elicit strong emotions conducive to comfort and safety (e.g., gratification and relaxation) that may incidentally excite or inhibit behavioral output, but it does not produce reward or punishment unless the anticipated outcome is found to be better or less aversive than expected. Adaptive learning depends on environmental conditions that provide enough order to foster reliable predictions together with sufficient change and variety to produce prediction dissonance. Either extreme of excessive regimentation or disorder (confusion) is inimical to instrumental learning. Consequently, given the deleterious effects of either extreme order or disorder, behavior therapy and training activities should be designed to strike a balance between the dog's need for order and its need for variability.

Chapter 1 provides a foundation of procedures and techniques used for basic training and the prevention or management of a variety of behavior problems. Basic training is an important aspect of cynopraxic therapy, playing a significant role in the treatment of virtually all behavior problems by improving interactive dynamics and establishing a platform of training and conditioning that complements and facilitates the implementation of behavior-therapy procedures. Emphasis is placed on the importance of integrating training activities into the home and bringing the dog under the control of everyday rewards and play—a process referred to as *integrated compliance training* (ICT). Although food reinforcement figures prominently in many cynopraxic training and therapy procedures, strong emphasis is placed on the pivotal role of affection and play for mediating behavior change via a normalization of human-dog interaction.

Play is particularly valued for its capacity to mediate cognitive and emotional transactions conducive to fairness, mutual appreciation, and interactive harmony. In addition to providing means for integrating and elaborating complex patterns of motivated behavior, play mediates powerful therapeutic effects by balancing emotional command systems, enhancing the human-dog bond, and improving the dog's quality of life. In general, attractive motivational incentives are used to facilitate a perception of control over significant events and enhanced power (competence and confidence).

Cynopraxic training efforts are distinguished by a focus on attentional functions (attending and orienting behavior), expectancies, and emotional establishing operations. Creating a framework of mutual attention and focus between the trainer and the dog is critical for communication, emotional transactions, and the bonding process. Attention control plays an important role in most dog behavior therapy and training procedures insofar as it mediates improved impulse control, social engagement, and autonomic attunement. Focusing training efforts on attending and orienting behavior is extremely efficient for establishing control over highly motivated behavior, especially when it is combined with the activation of potent conditioned and unconditioned appetitive and emotional establishing operations. For attention control to be maximally effective, it requires timeliness, ideally linking orienting stimuli, conditioned reinforcement, and establishing operations with the earliest intentional movements in anticipation of action, the target arc. Intensive orienting and target-arc training with positive prediction error exert a number of far-reaching benefits in the context of cynopraxic behavior therapy, virtually rebooting attentional functions, invigorating the social engagement system, and modifying preattentive biases. Rather than attempting to establish direct control over highly motivated and complex behavior by head-on means, many behavioral efforts are facilitated by first training a dog to orient toward the trainer, to attend (make sustained eye contact) in response to its name, and to pursue deictic signals or commands directing the dog's attention by gesture and gaze, and then building a small repertoire of reliable basic-training modules and routines (e.g., come, sit, down, stay, and controlled walking) via reward-based efforts incorporating both attractive and aversive motivational incentives. By means of basic training, attention control is progressively integrated with behavioral adjustments incompatible with undesirable activities and gradually unlinks attentional connections with competing sources of gratification and reward (distractions).

Chapter 2 contains foundation procedures and techniques for the control of inappropriate elimination, appetitive and ingestive behavior problems, and destructive exploratory activities. These basic areas of adjustment can exert a profound and enduring adverse effect on the bond and the dog's quality of life. Dog's that habitually eliminate in the house or destroy personal belongings may foster a high degree of familial resentment, often leading to excessive confinement, abusive punishment, or relinquishment. The section on house training completes a discussion on elimination problems begun in Volume 2, where several procedures and techniques used for controlling common elimination problems are discussed. In addition to methods used for controlling destructive behavior, various techniques are explored for the management and treatment of pica and coprophagy. The eating of nondigestible items is a significant health concern because it may result in life-threatening intestinal obstructions. Coprophagy also represents a health risk, but the greatest risk of harm is the damage such behavior does to the human-dog bond. Since coprophagy is highly offensive to the average dog owner's sensibilities, the disgust for the habit is easily transferred to the dog, especially in cases where small children affectionately interact with the dog. As a result, excessive or persistent coprophagy should receive prompt medical and behavioral attention aimed at resolving it, rather than be brushed off as an innocuous canine vice.

Chapter 3 explores the functional and dysfunctional significance of fear together with a variety of techniques and procedures used to

treat fear-related behavior problems. Maladaptive fear and anxiety figure prominently in the etiology of many adjustment problems as well as serious behavior problems. Once established, certain fear reactions may become virtually permanent, forming highly durable and extinction-resistant associations with conditioned eliciting stimuli. Dogs exhibiting such phobias are often treated with procedures aimed at reducing fearful arousal while exposure is organized in a way that encourages more effective coping strategies when faced with fear-eliciting situations. These procedures usually involve some form of graded interactive exposure or desensitization process carried out in combination with counterconditioning. Many fearful behavior patterns appear to operate under the influence of faulty prediction and control expectancies. Avoidance behavior occurring in association with fearful arousal may prevent a dog from discovering that its fear is unfounded, simply because the dog does not remain in the situation to recognize that it is not dangerous and that the anticipated aversive outcome does not occur. In essence, since the expected outcome never occurs, the avoidance response confirms the control expectancy. Consequently, response-prevention procedures are often used to block avoidance behavior with the goal of demonstrating to the dog that the aversive contingency no longer exists, thereby gradually extinguishing the avoidance response. Graduated exposure and response prevention are usually performed in conjunction with fear-antagonizing counterconditioning efforts and instrumental training efforts aimed at shaping behavior and expectancies incompatible with avoidance and fear. In addition to dysfunctional or faulty prediction and control expectancies, many common canine fears appear to stem from competency doubts arising in potentially dangerous or risky situations. Counterconditioning techniques are of little value in treating fears maintained under the anxiety and pessimism of competency doubts. In such cases, fear is treated by means of graded interactive exposure in combination with the progressive development of various skills needed to successfully control the feared situation (e.g., climbing stairs). Along with developing competent skills, the dog naturally becomes more confident and relaxed—a potent counterconditioning effect that follows from training and systematic skill development. In addition to social fears and avoidance, many aggression problems appear to stem from competency deficits, whereby the dog enters into provocative exchanges under an expectation of failure. Cynopraxic training enables dogs to cope more effectively with fear through the empowerment resulting from reward-based training. Learning to control the occurrence of attractive and aversive motivational stimuli promotes an improved sense of power that enables dogs to approach situations perceived as threats or challenges with a positive expectancy bias.

Chapter 4 addresses problems that occur in association with emotional agitation and distress at separation. The term *separation distress* has been chosen over the more commonly used term *separation anxiety* because the former term seems to capture more accurately the diversity of the emotional causes and varied presenting signs that characterize this collection of behavior problems. Although dogs distressed at separation often exhibit anxiety and worry, they also exhibit signs of frustration and panic, which are coactive states of arousal that likely arise from different causes and that may accordingly require different strategies of control and management. The term *separation distress* seems preferable to *separation anxiety* because the former is sufficiently general to encompass a varied group of coactive emotional influences, while remaining consistent with the experimental use of the term, denoting the propensity of young animals to become agitated or depressed when separated from maternal and sibling attachment objects or others with whom a state of reciprocal autonomic regulation or attunement has been established through interactive exchange. Also, separation distress appears to originate in a circuit dedicated to the generation of a special type of aversive emotional arousal associated with social loss, which is emotional activity that is sensitive to a variety of coactive excitatory and inhibitory influences, including anger, frustra-

tion, anxiety, and fear. Adopting the term separation distress also helps to distance separation reactivity in dogs from potentially misleading connotations and implications derived from the use of the term separation anxiety in child psychiatry.

Currently, the most common procedures used to control problematic separation distress are systematic desensitization and detachment training. These procedures are discussed in detail. Both procedures are hampered by compliance problems, on the one hand, due to technical and practical difficulties associated with the implementation of systematic desensitization and, on the other hand, stemming from the unwillingness of many dog owners to consistently impose restrictions on their dog's affection- and contact-seeking behavior. Various protocols emphasizing the importance of secure place and social attachments in the treatment of problematic separation distress are presented. Instead of breaking down the attachment between the owner and the dog or exclusively relying on techniques to reduce anxiety or other coactive symptoms presenting at separation, emphasis is placed on training and therapy procedures that improve the quality of the existing attachment and bond. Essentially, the goal of such training is replace dependent and insecure or nervous attachment dynamics and reactive patterns of separation behavior with a more mature and trusting bond while systematically shaping a more competent repertoire of separation behaviors. These objectives are achieved by means of various behavior therapy procedures, including the implementation of a program of variable and reward-dense separation exposures (planned departures), with the goal of organizing more secure separation expectancies and enabling the dog to endure stressful separations without becoming overly reactive or panicked. Training activities that increase social trust and secure attachments (comfort and safety) are central to the effective treatment of separation-related problems.

An increased vulnerability to separation distress (and aggression) may be causally related to stressful insults occurring at a formative stage of development. To evaluate possible causal linkages between prenatal and postnatal stress on developing behavior, relevant lines of neurobiological research are reviewed, which is a theme that is continued in the context of aggression problems in Chapter 8. Interestingly, separation-distress problems often share with serious aggression problems an element of panic (reactive incompetence) arising in association with social exchanges and transactions that threaten a loss of comfort or safety. Both sets of adjustment problems present with a similar autoprotective urgency, but, of course, operating under diametrically opposed incentives aimed at producing quite opposite effects, yet sharing equally reactive and incompetent means, namely, efforts to increase proximity (separation distress) versus efforts to decrease proximity and contact (intrafamilial threats and attacks). Separation distress and intrafamilial aggression appear to share a common hub of vulnerability and autonomic dysregulation that develops in the process of forming regulative attachments with people, making such problems and their treatment preeminently cynopraxic in nature, and underscoring the necessity of therapy and training activities to reduce social ambivalence and entrapment tensions, promote comfort, safety, and power (security), and secure place and social attachments. Although genetic and stress-related neurobiological factors probably play a predisposing role in the development of many separation-distress and aggression problems, giving owners appropriate counseling and providing at-risk puppies with supplemental training may substantially help to ameliorate or prevent some of these problems. Initiating protective and counteractive measures at an early stage in the epigenetic process is more likely to succeed than belated heroic efforts performed after the problem behavior is well established. Of particular importance in this regard is the provision of secure environmental circumstances, the development of a trusting bond, and training efforts to help the puppy or dog learn how to cope more competently with the periodic loss of comfort or safety resulting from social separation.

Chapter 5 deals with various procedures and protocols used for controlling and managing excessive behavior. Compulsive excesses

are under the control of a variety of evoking and exacerbating influences, many of which remain obscure. Dogs prone to motor compulsions are often highly active and intolerant of frustration (choleric or c-type dogs), whereas dogs showing self-directed compulsions (e.g., licking) may be particularly vulnerable to the adverse effects of anxiety and depression (melancholic or m-type dogs). One theory suggests that compulsive actions may trigger reward circuits that help to maintain the activity in the absence of other sources of extrinsic reward, perhaps reflecting a failure of the dog to obtain adequate reward in more adaptive ways. Control and management programs frequently include efforts to remove or minimize adverse sources of social (interactive conflict and tension) and environmental stress, consisting of significant events perceived as uncontrollable, while introducing training activities designed to normalize executive cognitive functions (attention and impulse control). Play therapy is often employed to balance emotional command systems, provide a source of reward and gratifying interaction with the owner, and increase object interest and environmental exploratory activities. Finally, a variety of behavior-therapy and training procedures are described for the treatment of specific compulsive behaviors, including diverting or disrupting techniques, counterconditioning, shaping incompatible behaviors, bringing the compulsive behavior under stimulus control, exposure with response prevention and blocking, and, in the case of refractory or physically harmful compulsions, inhibitory techniques.

Impairments associated with compulsivity and hyperactivity appear to represent the opposite ends of a common continuum or spectrum related by functional significance. Whereas compulsive dogs tend toward introversion, repetitive self-directed activities, and intolerance for anxiety and danger, hyperactive dogs are typically extraverted, tend toward highly variable and other-directed activities, exhibit a high degree of fearless (bold) behavior, and show intolerance for frustration and a propensity toward impulsive aggression. Whereas compulsive dogs have trouble controlling autodirected activities, hyperactive dogs exhibit difficulty controlling allodirected activities, exhibiting executive disturbances affecting their ability to regulate ongoing activity voluntarily. These correspond to passive and active modal activities launched to cope with drive-activating stimulation but disengaged from competent prediction-control expectancies, giving compulsive behavior and obsessional appearance. The compulsive-impulsive continuum may represent a significant temperament dimension that has been differentially selected and preserved during the dog's evolution. Depending on environmental conditions, the traits of compulsivity or impulsivity may be variably adaptive or maladaptive with respect to survival. Traits associated with hyperactivity and impulsive behavior may be conducive to survival under conditions of adversity and scarcity, whereas compulsive traits may be more adaptive and useful under conditions of plenty, suggesting the possibility that phylogenetic survival modes and quality-of-life factors may play a significant role in the expression of such traits (see *Phylogenetic Survival Modes* in Chapter 10).

The executive attention and impulse-control deficiencies associated with hyperactivity are improved by reward-based integrated compliance training aimed at shaping improved attending and waiting behaviors. Explicit training of attention skills appears to focus and invigorate impaired executive impulse-control functions. As a result of the hyperactive dog's preference for novelty and surprising events, attention training makes use of prediction dissonance (i.e., varying the size, type, and frequency of attractive outcomes) to build attention and impulse control. Without gaining conditioned control over attention, there is little possibility for effectively and consistently interrupting highly motivated activities, activating antagonistic appetitive or emotional establishing operations, or prompting incompatible instrumental behavior. In addition to attention therapy, time-out, response blocking, overcorrection, and posture-facilitated relaxation training are employed to help discourage behavioral excesses. Perhaps the most valuable strategy for controlling and managing hyperactivity

and associated problems is to integrate attention and impulse-control training into the context of play.

Chapters 6, 7, and 8 are dedicated to exploring the etiology, safe management, and treatment of a broad spectrum of common aggression problems. Aggression problems are distinguished by a significant factor of risk and danger to the cynopraxic therapist/trainer, the client family, and the public at large. Calculating and managing these risks in an informed and professional manner is an important aspect of interventions involving aggressive dogs, particularly involving dogs with a history of delivering hard and damaging bites. Assessment, decisions on whether to accept cases, articulation of working hypotheses, selection of a course of therapy and training, evaluation of the benefits of training, and prognostic opinions require that the cynopraxic therapist possess a significant amount of technical knowledge and direct experience handling aggressive dogs. In addition to bringing competence to the situation, the cynopraxic therapist/trainer must be able to convey a realistic picture of the risks involved and the likely benefit of training. The owner needs to be made aware that the control and management of aggression problems is an art that is prone to many uncertainties and vagaries with respect to outcomes, but may nonetheless help to improve the dog's behavior and reduce the risk of aggression by instituting appropriate and effective precautions, reducing interactive conflicts and tensions, increasing the occurrence of prosocial behavior, and improving the dog's confidence and ability to relax. Nevertheless, the risk cannot be entirely eliminated, and the dog might bite at some point in the future, despite the most conscientious efforts. On principle, serious aggression problems cannot be cured but many can be successfully controlled by means of preventive and preemptive management, behavior therapy, and training. This limited prognosis is a far cry from what most owners want to hear about the fate of their aggressive dog, but it is something that needs to be driven home with no waffling or exceptions—there will always be some risk for a similar or worse bite in the future. To be successful requires of the family a lifelong commitment to preemptive management and training. In accordance with the dead-dog rule (training objectives should not be guided by assessment markers that a dead dog can satisfy), successful training and therapy are not measured merely by the absence of an aggressive episode for some period (dead dogs do not bite), but more significantly success is measured by an increase in socially competent, cooperative, and friendly behavior in situations that previously provoked reactive incompetence and aggression.

The dog's dependency on human prerogative and fickleness for obtaining its survival needs places significant pressure on it to learn how to anticipate and control human contingencies of reward and punishment. As a result, social interaction that lacks adequate predictability and controllability may produce significant conflict, stress (anxiety and frustration), and social ambivalence, potentially exerting a persistent deleterious effect on the dog's ability to organize competent social behavior and trusting expectancies regarding social change. The dog cannot simply leave a disorganized and emotionally destructive situation but is forced to cope and adjust to it (entrapment). Unable to leave the relationship and pressed to the limits of its ability to cope with its vagaries and inconsistencies, the predisposed dog may become progressively agitated, irritable, intolerant, emotionally rigid, and reactively incompetent. Consequently, the process of cynopraxic counseling and therapy is guided by a principle of fairness in which both the family's expectations and the dog's needs and limitations are acknowledged and given appropriate weight and consideration when resolving interactive conflicts and tensions that interfere with the development of a trusting bond. Finally, quality-of-life issues need to be carefully assessed and addressed, insofar as they adversely affect the dog's ability to develop a secure place and social attachments as well as predispose it to increased irritability and emotional reactivity. Dogs that are sick, in pain, improperly fed, inadequately exercised, denied play and variegated forms of environmental stimulation, excessively confined or isolated, and so forth may show signs

of increasing irritability and progressive autoprotective insularity and reactive intolerance toward social interference and contact.

How dogs cope with social ambivalence and entrapment dynamics depends on a variety of predisposing factors, including heredity, prenatal and postnatal stress, and the quality of early socialization and training activities. In addition to impairing cognitive functions, excessive emotional stress, inadequate or inappropriate socialization, and abusive-traumatic handling may focalize persistent disturbances in vulnerable emotional command systems (anger/rage system). Potentially serious emotional disturbances of this kind may be produced by abusive social transactions involving the simultaneous elicitation of high levels of fear and anger. In extreme cases, a history of abusive handling may impair a dog's ability to modulate aggressive arousal in response to even mildly provocative stimulation. Under such circumstances, fear or anger may spark a spiraling and rapidly escalating state of emotional reactivity (panic), thereby setting the stage for an reactive attack arising from a dog's incompetent attempt to cope. In moderate cases, abusive transactions may predispose a dog to conflict-related stress (anxiety and frustration) associated with close social contact. Consequently, the dog may exhibit an increased sensitivity to anxiety or frustration occurring in association with minor intrusions and losses of comfort (frustration) or risks to safety (anxiety), thereby intensifying autoprotective behavior and increasing the dog's readiness to threaten or bite. In all cases, a dog's ability to form a trusting bond with humans is significantly harmed by abusive and traumatic handling. The extent of harm and the type of emotional disturbance that such handling produces depends on a dog's temperament, the severity of the emotionally destructive transaction, and the presence or absence of reconciliation efforts and ameliorating influences (e.g., supplemental socialization and training).

A failure to establish or to maintain a trusting bond appears to play a prominent role in the development or exacerbation of many domestic aggression problems. The rehabilitation of an aggressive dog is not so much about imposing a structure of dominant and subordinate roles (although the necessity of setting appropriate limits should not be neglected) as it is concerned with the restoration of interactive order and harmony by means of affectionate, appetitive, and playful interactions, with the goal of increasing interactive cooperation, familiarity, and trust between the owner and the dog. The comfort and safety associated with orderly and nurturing interaction serve to increase a dog's enjoyment of social contact as well as to improve its tolerance for intrusive interaction. In addition to facilitating fairness and friendliness, play appears to enable dogs to cope with social uncertainty in a more positive way. In general, the dog that has formed trusting expectancies toward the owner is more likely to exhibit tolerance and restraint when exposed to provocative stimulation than is the dog that is uncertain or socialized to distrust the owner. Dogs that have formed a trusting bond appear to give the owner (and others) the benefit of doubt when faced with uncertain situations rather than interpreting provocative or unexpected transactions in worst-case terms and jumping to threatening or retaliatory conclusions. In the absence of a flexible and trusting bond, human-dog interaction is prone to degenerate, resulting in varying degrees of persistent uncertainty and suspicion, anger and irritability, distrust, and reactive incompetence. These sorts of social expectancies and emotional establishing operations combine to lower reactive thresholds and increase the likelihood that the dog might threaten or attack in response to innocuous social intrusions. Identifying puppies that show reactive tendencies at an early age or exhibit other indicators of increased risk (low fear and anger thresholds) and providing puppy owners with counseling on proper training and management may protect against the development of more serious aggression problems later.

In recent years, there has been a growing professional use and interest in electronic devices for dog-training and behavior-modification purposes. Unfortunately, scant little technical information has been written on the proper use of such devices in the context of

canine behavior therapy and dog training—a situation that is especially problematic with respect to radio-controlled collars. With significant trepidation and concern about the potential for abuse, Chapter 9 addresses the use of electronic devices in the context of problem solving and training. When properly used, such devices and techniques can be highly effective and humane for the control of certain otherwise intractable or difficult-to-control behavior problems. It is the author's sincere hope that cynopraxic trainers will use electronic devices, and other tools that produce aversive stimulation and startle, sparingly and with an appropriate degree of restraint and respect for the dog and not fall into the trap of reaching for an electronic collar whenever a tough problem presents itself. Aversive tools and techniques can be extremely useful as motivational incentives to promote behavioral change in the context of reward-based training efforts, but they should not become an alternative to affectionate, playful, and creative attractive incentives. Aversive procedures should be applied in conformity with the dead-dog rule (see *Dead-dog Rule* in Volume 2, Chapter 2), the least intrusive and minimally aversive (LIMA) principle, and cynopraxic goals.

As a philosophy and method for investigating natural phenomena, science is generally a powerful and productive way for acquiring, organizing, and putting knowledge to work. Scientifically informed and coherent procedures and protocols are more likely to work and survive the test of time by virtue of their explanatory value, efficacy (combining simplicity, efficiency, and effectiveness), and adaptability, that is, their ability to continuously adjust and improve in accord with scientific progress. However, despite the obvious value of the scientific method for obtaining descriptive and causal information, the scientific method suffers from a lack of serious regard and sensitivity for some of the more subjective and emotional aspects of human-dog interaction. Interactive exchanges (particularly problem behavior) are not simply factual events but emotional transactions with various levels of meaning and significance that will forever slip through the Cartesian grid. In addition to practical criteria of success, canine behavior-therapy and training procedures must be applicable to the domestic situation, offer benefits for both the human-dog bond and the dog's quality of life, and be humane. As a result of these special requirements, scientific means are tempered and given humane direction by confining their use to the pursuit of cynopraxic goals and vision.

In writing this series, the author has directed a significant amount of attention toward developing a theory compatible with scientific and cynopraxic interests in order to establish a firm but flexible foundation for the advancement of canine behavior counseling therapy and training. Chapter 10 draws together the central elements of cynopraxic bonding, training, and biobehavioral theory. These theoretical concepts and principles have been discussed and elaborated to various degrees throughout the *Handbook of Applied Dog Behavior and Training*, and readers should refer to relevant sections in Volumes 1 and 2 for additional discussion regarding cynopraxic bonding theory, philosophy, and ethics. The goals of cynopraxic theory are to clarify cynopraxic processes, to develop an account of learning that is compatible with cynopraxic objectives, and to establish a simplified and coherent language for describing organizational learning processes associated with cynopraxic training and therapy. Cynopraxic theory incorporates a pragmatic principle of fallibility, acknowledging the possibility of error in its inferences and explanations, thereby embracing a readiness to adjust in accordance with future scientific progress; however, the dyadic goals of cynopraxic training and therapy are considered indisputable, namely, enhancing the human-dog bond while improving the dog's quality of life. The study of cynopraxic bonding, training theory, and practice arts is referred to as *cynopraxiology*.

No compendium of instructions can take the place of competent professional help for properly assessing canine behavior problems and prescribing behavior-therapy and training recommendations. The assessment procedures, instructions, guidelines, recommended devices and uses, behavior-therapy protocols,

and training techniques described in Volume 3 assume that the user is appropriately experienced, knowledgeable, skilled, and qualified to apply them in a selective, competent, and safe manner. The proper selection and implementation of behavior-therapy and training procedures require that the behavior practitioner possess a thorough appreciation of their therapeutic benefits, risks, and potential adverse side effects. Aggression problems are particularly risky and problematic and should only be treated under the supervision of a competent professional qualified to give such advice and instruction. Improperly treated aggression problems may rapidly worsen, becoming more dangerous and difficult to manage or control. While Volume 3 offers educational information that may be of significant value to dog owners and others interested in dog behavior, it is not intended as an alternative to professional cynopraxic counseling and supervised treatment activities.

Acknowledgments

Writing a book is the culmination of many influences and the help of many people. I have enjoyed the encouragement and support of numerous individuals who have given me valuable advice and inspiration, engaged me in useful discussion, or have simply been helpful in tracking down information or other small matters and details. Listing and individually thanking all of these wonderful people would be impossible and not without the risk of overlooking someone in the process. So, instead of thanking some of you, I hope that it suffices to thank all of you for your unselfish help. I also thank the clients who have entrusted me with the responsibility of helping them work through behavior problems with their dogs. The concept of cynopraxis and many of the procedures and protocols described in Volume 3 could not have been developed without their confidence and participation. A special thank you is due to Christina Cole for her many sacrifices on by behalf and her steadfast support of the project from its inception to completion.

Cynopraxic Training: Basic Procedures and Techniques

PART 1: FOUNDATIONS AND THEORY

BENEFITS OF CYNOPRAXIC TRAINING

A coevolutionary process of mutual exchange and adjustment appears to have prepared a biological bond between people and dogs making them compatible to live together in the home (see *Coevolution, Play, Communication, and Aggression* in Chapter 6). The training process helps to perfect and intensify this evolutionary bond while enhancing our mutual appreciation of one another. In addition to enhancing the ability of people and dogs to relate, training serves the obligatory role of improving the quality of canine life under the constraints of domesticity. Learning to come reliably when called or to walk on leash without pulling, along with sundry other useful and critical behaviors, provides an effective and safe means to liberate dogs from the drudgery of excessive confinement and an overly narrow social and environmental life experience. In effect, no activity offers more potential benefit for enhancing the human-dog bond and improving the dog's quality of life than training (see *Cynopraxis: Training and the Human-Dog Relationship* in Volume 1, Chapter 10).

The dog's close social interaction with people requires that it learn to accept certain inevitable limits and boundaries, respond reliably to a number of basic commands, and exhibit habits and manners conducive to domestic harmony. These general behavioral objectives are integrated into everyday training activities, thereby strengthening the social connection between the owner and dog as well as facilitating interactive harmony and the development of cooperative behavior. Learning to defer and comply with owner directives is essential for a dog to become a successful companion. A dog's proper adaptation to life with people demands responsible discipline and the establishment of appropriate limits and boundaries. Without boundaries and social distance, a relationship is not possible. Whereas assertions of dominance serve to establish social distance and set limits upon the expression of unacceptable behaviors, leadership promotes more acceptable and cooperative behavior by means of affectionate encouragement, play, food giving, and other nurturing activities. Deference to limit-setting actions and assertions of control promotes affectionate and voluntary cooperation, thereby providing the necessary preconditions for effective leadership. Training helps dogs to learn that deferring and following the owner's lead optimizes their ability to obtain comfort and safety. By learning to follow rules happily and obediently, social conflicts are reduced and a leader-follower bond based on affection, communication, and trust is allowed to

TABLE. 1.1. Benefits of cynopraxic training

Provides a foundation of communication based on predictable and controllable exchanges between the owner and the dog
Provides the owner with effective management and control skills
Systematically balances the triune bond consisting of dominance, leadership, and nurturance
Improves the dog's attention and impulse-control abilities
Promotes affection and mutual appreciation
Establishes habits conducive to domestic harmony
Enhances social adjustment, cooperation, and competence
Promotes relaxation and a sense of well-being
Builds confidence and trust

form—an essential foundation for the development of a healthy human-dog relationship (Table 1.1).

Training promotes behavioral change by manipulating contingencies of reinforcement and punishment. For dogs, social and environmental predictability and controllability are necessary preconditions for security, contentment, and well-being. A failure to predict and control significant attractive and aversive events adequately gives rise to varying degrees of disstress in the form of anxiety and frustration. Of course, when present in limited amounts, anxiety and frustration are conducive to enhanced adaptive success (e.g., prediction error), but in situations where excessive and persistent social conflict and interactive tensions are present, a dog's ability to function in an organized way may gradually deteriorate or break down (see *Experimental Neurosis* in Volume 1, Chapter 9). Dogs living under stressful and inescapable conditions of social disorder and adversity are vulnerable to develop a wide range of behavioral adjustment problems and disturbances (see *Dysfunctional Social and Environmental Influences* in Volume 2, Chapter 2).

Interactive conflict and tension between the owner and dog often develop in the context of antagonistic control interests. In many daily situations, the owner stands between the dog and the acquisition of a variety of highly valued rewards or prevents the dog from escaping or avoiding aversive events, often occurring as the result of engaging in rewarding activities forbidden by the owner. Dog owners often dedicate a tremendous amount of energy to regulate the appetitive interests of their dogs by employing a variety of active and passive control strategies, primarily involving interactive punishment and confinement. Active punitive strategies are particularly problematic since they are often used without much, if any, subsequent concern for showing the dog how to obtain the gratification that it is seeking while engaged in the forbidden activity. Limiting the dog's behavior by means of passive control strategies (e.g., crating and tethering) in the absence of constructive training efforts can be equally harmful to the human-dog bond and the dog's quality of life. In both instances, the dog's ability to establish predictive control over appetitive and social rewards needed to optimize its adaptation and security (comfort and safety) are impeded or blocked. Setting limits by means of varying degrees of force (dominance) or restriction can be highly beneficial for the dog, but only if the dog is simultaneously shown alternative means to obtain the gratification that it seeks to obtain. Impeding the dog's ability to escape or avoid an aversive situation by punishing an unacceptable mode of behavior (e.g., separation distress barking or whining), but without helping it to discover an alternative way to escape, avoid, or cope (e.g., providing it with an alternative or compensatory source of reward) from the aversive state (e.g., isolation and loneliness), may only tend to generate additional distress and focalize a point of ongoing conflict and tension between the owner and dog. Thwarting the dog's ability to obtain appetitive and social rewards by punishing unacceptable behavior (e.g., jumping up, barking, digging, chewing, pulling, and mouthing), without at the same time teaching the dog more acceptable means to produce equal or better reward opportunities, only serves to focalize conflict and tension between the dog and the owner over the acquisition and control of those thwarted reward opportunities.

From the cynopraxic point of view, these interactive conflicts and tensions oppose the objectives of interactive harmony and mutual appreciation, and, as such, represent the specific target areas of therapy efforts aimed at enhancing the human-dog bond. In addition, interactive conflicts and tensions precisely define the various social and biological needs that are not being adequately met by means of the relationship, thereby offering opportunities to improve the dog's quality of life significantly. Cynopraxic training is based on the assumption that interactive conflicts and tensions are resolved by teaching the dog alternative and mutually acceptable means to obtain the sought-after activities and rewards. In the process of dog owners being counseled about the sources and causes of interactive conflict and tension, owners learn about canine needs and become progressively appreciative of them, especially as they learn how to use them constructively in the process of improv-

ing their ability to control the dog via integrated compliance training (ICT). ICT refers to a training strategy that objectifies interactive conflicts and tensions as potential sources of reward for the dog, on the one hand, and opportunities for enhancing owner control efforts, on the other—a win-win exchange in the service of cynopraxic goals. ICT promotes social competence, cooperation, and trust via the mutual success of the owner and dog to establish predictive control over each other's behavior in the process of seeking and gratifying their individual needs by means of gratifying the needs of the other. Instead of standing in the way of the dog's appetitive and emotional gratification (comfort and safety), the owner becomes a cooperative and trusted partner in the process of acquiring attractive outcomes and avoiding aversive ones. The resultant reduction in interactive conflict and tension gives rise to social competence and trust, increased confidence and relaxation (the cognitive and emotional corollaries of social competence), and a foundation for interactive harmony and mutual appreciation. These various elements and outcomes of training play a significant role in cynopraxic counseling and canine behavior therapy, providing a platform of preliminary cognitive and emotional organization for approaching a wide spectrum of canine behavior problems.

Organized training activities not only systematically influence overt social behavior, they also serve to produce a broad spectrum of emotional changes (Rolls, 2000) (Figure 1.1). Classical conditioning and instrumental learning processes interact at various levels of cognitive and emotional organization, with appetitive and emotional attractive and aversive stimuli instigating a variety of emotional and motivational changes (see Rescorla and Solomon, 1967). In addition, a dog's cumulative successes or failures to control significant attractive or aversive events are reflected in persistent emotional changes and its disposition to learn and adjust. For example, establishing reliable predictive control over attractive and aversive events appears to promote enhanced mood and optimistic expectancy biases—a "better state" of being (Wyrwicka, 1975). Finally, training activities improve

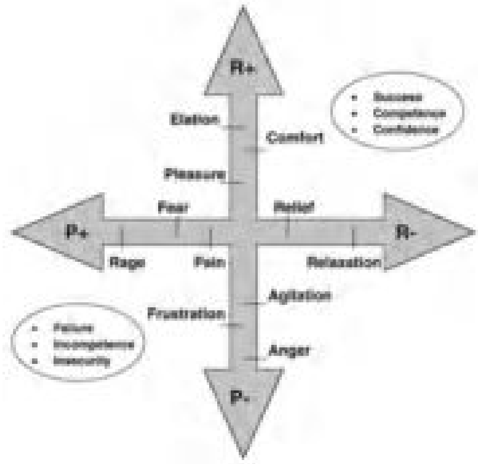

FIG. 1.1. Training events are associated with the production of a variety of emotional states that exert pronounced effects on mood and reactive behavior (see Rolls, 2000).

attentional functions and impulse-control abilities, as well as reduce adverse anxiety and frustration via increasing competence, confidence, and relaxation. Essentially, all training activities function as attention and impulse-control therapies in the context of developing useful behavior. As the result of effective training, dogs appear to adopt a more focused, relaxed, secure, and trusting attitude toward the social and physical environment, helping them to cope more effectively with conflict or emotionally stressful stimulation.

In addition to the various benefits of cynopraxic training for dogs, owners stand to gain from the experience. As the result of training their dogs, owners learn how to observe behavior, to appreciate a dog's biological and emotional needs, to communicate more effectively, and to develop a more informed estimation of a dog's cognitive capacities and limitations—all leading to a better relationship with the dog. Also, during introductory lessons, owners learn basic learning principles while practicing skills and techniques of behavior modification. In addition to reducing interactive conflict and tension, the progress and success that owners experience during these early lessons (e.g., training a dog to walk on-leash, to come

when called, to sit and lie down on command, and to stay) help to generate a more constructive and optimistic attitude about the dog's responsiveness to behavior therapy efforts.

Specific Benefits of Various Exercises

Dogs with behavior problems often benefit from systematic training before advancing to the implementation of more specialized behavioral procedures. In addition to general benefits, the practice of various trained exercises and tasks provides specific benefits relevant to the enhancement of canine behavior therapy efforts:

Orienting and Attending Response

Training the dog to reliably turn and focus its attention toward the trainer is a vital aspect of behavior control and management. In the absence of attention control, it is not possible to efficiently control impulsive behavior or responses operating under the influence of extraneous sources of reward (distractions). The direction of a dog's attention is defined by moment-to-moment motivational changes and intentional shifts preparing it to act on the environment. All purposive behavior is determined by shifts of attention, intention, and action functionally integrated and directed toward the environment in response to some motivationally significant imperative or impulse. Orienting and attending behavior promotes organized behavior. Without an ability to orient and selectively focus attention, the senses would be overwhelmed by the surrounding flux of environmental stimulation. As an adaptive interface between internal imperatives (establishing operations) and the external environment (a field of activity and choice), attention mediates action with the goal of increasing environmental predictability and control. Attention, intention, and action are intrinsically dependent on one another via a complex network of modulating interactions and feedback relations that are strongly influenced by the complementary effects of reinforcement (success) and punishment (failure). Attention therapy plays an important role in the treatment of a variety of behavior problems occurring in association with impulse-control deficits. Attention is related to impulse control as a hinge is to a door, such that the hinge defines the full range of the door's movements. Controlling a dog's attention is virtually tantamount to controlling the full-range of the dog's behavior, whereas losing a dog's attention to environmental distractions leverages control away from the trainer. In extreme cases of behavioral disorder, a dog's attention may become "unhinged" as attention and orienting responses become overstrained and disturbed, resulting in reactive and impulsive behavioral disorganization (see *Locus of Neurotogenesis* in Volume 1, Chapter 9).

Sit-Stay and Down-Stay

The sit response is an instrumental control module that every dog owner should master and practice with their dog under a wide variety of situations. Sitting on command is rapidly conditioned, produces a significant amount of control, and requires a minimal amount of instruction. Stay training strengthens inhibitory processes and impulse control, increases delay of gratification capacities, and promotes deference to owner control efforts. Training dogs to sit and stay on command for food, petting, and other rewards in everyday situations provides a simple and effective way to obtain improved cooperation and compliance. The rapid success and control produced by training dogs to sit and stay may have a highly beneficial effect on owners needing a ray of hope. In the late 1960s and early 1970s, David Tuber and Victoria Voith happened upon the value of preliminary reward-based sit-stay training in the context of treating fear-related behavior problems. As Voith recounts,

> Firstly, it gave the owners something to do between the first and second visits (which were a week apart). This gave us time to discuss the problem and develop a detailed, individual behavior modification program for that case.

> Secondly, most of our programs involved a classical conditioning component designed to change the emotional/physiological response to specific stimuli, e.g., loud noises, frightening people or other animals, distress responses etc. It was advantageous to have the dog stationary as the stimuli were introduced and it was essential that learning sit-stay be fun, non-punitive, not forced in any way and pleasant. No leash correction, no stern voices. The reward for the act of sitting and then remaining so for progressively longer periods of time was a mouth-watering tidbit. Needless to say, the dogs learned to sit and stay within a few minutes. But the dogs were not only learning an operant response; they were associating pleasant experiences (delicious food, praise from owner) with the verbal cue "sit" and the act of being in a sit-stay. A week of simple sit-stays was also teaching the owner how dog's learned.
>
> When we saw the dog a week later, the sit-stay (or down-stay) kept the dog in one spot, allowing us to gradually introduce other stimuli and to easily pair food rewards with the introduction of stimuli. In addition, the verbal cues and the act of sitting and staying also acted as conditioned stimuli, evoking pleasant emotional responses. The pleasant emotional states associated with sit-stay contributed to the classical counterconditioning paradigm and even could be a conditioned reinforcer when food was no longer presented. (Voith, personal communication, 2002)

The method was further developed and refined by Voith while she directed the Animal Behavior Clinic at the University of Pennsylvania. Voith's Sit-Stay Program involves dozens of discrete sit-stay tasks and variations of increasing difficulty (Voith, 1977b; Marder and Reid, 1996) (see Appendix A). Although not always appropriately credited to her as the originator, variations of her Sit-Stay Program and her Nothing in Life Is Free (NILIF) protocol (Voith, 1977a) are widely recommended by veterinarians, trainers, and applied dog behaviorists as a preliminary platform of control for carrying out counterconditioning procedures. Practicing sit-stay variations under varying environmental and motivational conditions promotes better attention and impulse control abilities. Together with the wait, controlled walk, coming when called, and down-stay exercise, sit-stay plays a prominent role in ICT. Finally, the sit-stay is frequently used as an incompatible response in various instrumental countercommanding procedures.

Controlled Walking

Every dog should be trained to walk on leash and collar without pulling. Such training is imperative in the case of dogs exhibiting behavior problems associated with attention and impulse-control deficiencies. Training the dog to walk on a slack leash is a necessary step toward enhanced deference to trainer-control efforts while in the presence of highly distracting or provocative stimuli. Since the dog must actively defer to every step and change of direction that the trainer takes, without impulsively chasing after other animals or objects that may be encountered, the process yields rapid and significant attention and impulse-control enhancement, especially if it is combined with sit and sit-stay training. Controlled walking consists of training the dog to walk at the left side with its hip aligned with the trainer's left leg. Although the dog can move back from this position, it cannot move ahead of it. Training the dog to walk on leash in a controlled manner allows the trainer to move the dog about in a controlled manner. This enhanced control of movement is useful when exposing the dog to potentially provocative situations, such as during graduated exposure procedures. A dog that is responsive to leash control can be more readily moved toward or away from provocative stimulation, thereby increasing the trainer's ability to perform controlled exposures to target stimuli during counterconditioning and desensitization efforts. The ability to precisely control exposure gradients decreases the risk that a dog will react adversely during such training activities. In combination, these aspects of controlled walking significantly enhance the effectiveness of response prevention and counterconditioning procedures. Training a dog to defer to leash limits and to follow prompts and signals while on leash appears to enhance significantly the leader-follower bond and the dog's overall willingness to cooperative. Finally, a major benefit of training a dog to walk on leash without pulling is that it is likely to

result in the dog getting more walks and going more places with the owner.

Quick-sit

The quick-sit is conditioned in the context of controlled walking. The dog is trained to sit rapidly and without hesitation, and remain in the sit position until the trainer releases it. Consequently, in addition to sitting rapidly, quick-sit training places a high priority on conditioning the dog to remain in the sit position regardless of environment distractions. Quick-sit is an emergency response that means "sit and stay," period. The quick-sit is practiced under a variety of increasingly distracting and adverse conditions. The training exercise promotes alertness, enhanced attention and impulse control, and readiness to respond cooperatively and obediently under adverse conditions. The exercise is useful as platform for various behavior-therapy procedures and is particularly helpful in the case of dogs exhibiting offensive aggression toward other dogs or various chasing problems.

Down, Down-Stay, and Instant-down

Down training builds on control established during sit-stay training. The down-stay is used in situations requiring that the dog defer and stay in a relaxed manner for long periods. Down training is particularly useful in the control and management of overly active and intrusive dogs. In adult dogs, resistance and oppositional tendencies may be momentarily intensified during down training. Down training provides a means to work systematically through such resistance constructively. In addition to down and down-stay, impulsive dogs should be trained to go to a spot and lie down on command without hesitation. Similar to the quick-sit, the instant-down promotes increased cooperation and compliance to command in emergency situations.

Starting Exercise

Dogs should be trained to a high degree of proficiency to move to the trainer's left side and sit there. The starting exercise requires that the dog turn away from distracting or arousing stimuli and either hook around at the trainer's left side or move to the rear of the trainer before crossing over to the left and sitting automatically. The control established by means of the starting exercise has many applications, such as establishing or enhancing control during greetings with visitors or bringing the dog back under closer control while on a controlled walk. All the basic elements of attention training are incorporated into the starting exercise.

Heeling

As an organized and coordinated activity, heeling requires that both the trainer and the dog concentrate on the actions of each other, promoting enhanced connectedness, common purpose, and leader-follower bonding. While heeling, the dog remains close at the trainer's side, keeping pace with abrupt and frequent changes of pace, following directional changes, and responding to stop and go actions by sitting or standing up. These various coordinated movements reflect the development of a signaling system of increasing subtlety and refinement. In contrast to the passive nature of static tasks such as sit-stay and down-stay, controlled walking and heeling are dynamically organized, consisting of responses sequentially entrained in accordance with the trainer's movement and body position relative to the dog. In an important sense, heeling is *moving-stay* exercise. The high level of positive reinforcement and inhibitory training associated with the conditioning of controlled walking and heeling provide a platform of control that competes with undesirable behavior, making counterconditioning efforts and the differential reinforcement of other, alternative, or incompatible behavior more efficient and likely to succeed.

Recall and Halt-Stay

A dependable willingness to walk on leash without pulling and to come when called is the mark of a successfully socialized and trained companion dog, whereas persistent pulling and refusal to come when called is the mark of an untrained or improperly trained dog. The amenable habit of staying close when off leash or coming when called despite

the presence of competing distractions signifies the presence of a leader-follower bond of sufficient strength to withstand the intrusion of external diversions and temptations. Freeze training is a routine aspect of recall training. When properly introduced and conditioned, the halt-stay module serves to interrupt highly motivated behavior decisively, enhancing the trainer's control over seeking excesses and dangerous impulsive behavior. Instead of running out of control when off leash, dogs should be trained to orient, come, or halt instantly in place and wait where they stand until *reached, recalled,* or *released* by the trainer—the 3 R's of halt-wait training. Effective recall and halt-stay training provides dogs with numerous quality-of-life benefits, serving to free them to enjoy the environment while minimizing the risk of harm to them as the result of being off leash. The recall and halt modules are critical and should be trained to a high degree in advance of letting dogs off leash to play and enjoy an open or public environment. Even in the case of dogs not let off leash in such places, the recall and halt modules should be trained to a high degree of reliability to prevent accidental injury as the result of bolting from the car or house. Many common problems are obviated by solid recall and halt-stay training.

BEHAVIORAL EQUILIBRIUM

Basic training should be performed with an eye toward balancing exercises with opposites in order to prevent a dog from becoming overly expectant and reliant on some set of behaviors to the exclusion of others. A dog that is repeatedly prompted to lie down from the sit, but not the other way around, might prove more difficult to train to perform the reverse action of sitting from the down; similarly, a dog that is exclusively trained to sit, without being occasionally prompted to stand, may be more difficult to train to hold a stand or stand-stay later on. Consequently, basic exercises are balanced by patterning their sequence in various ways. For example, heeling closely at the trainer's side is balanced by opportunities to walk freely. Staying in place is balanced by opportunities for increased activity, including heeling, recall, and release for play. Movement away from the trainer is balanced with stopping and returning exercises. Taking objects from the hand is balanced by prompting the dog to release them. Fetching objects is balance by training the dog to avoid certain objects. Waiting at doorways is balanced by release cues, move-away signals, or come-along signals. Lying down is balanced by having the dog sit or stand from the down position. The sit response is balanced by prompting the dog to stand. The automatic sit is balanced by an exception cue signaling the dog to stand or stand-stay instead of sitting. Going to heel (start and finish) is balanced by having the dog learn to go back to front from the trainer's side. A balanced repertoire of directional tasks can be extremely useful. Dogs can be easily trained with vocal signals and hand prompts to stop, back, move forward, turn left, turn right, and turn about. Not only do such activities improve a dog's attention abilities, they also enhance the trainer's ability to precisely control the dog's behavior at a distance. Many additional examples of behavioral equilibrium could be listed following the same basic pattern in which the type, direction, and function of any given item in a dog's repertoire is matched with its behavioral opposite.

Balance should also be considered when modifying common nuisance problems. When dogs are trained to limit excessive barking, they should also be trained to bark on signal. Similarly, dogs trained not to jump up should also be trained to jump up on cue under appropriate circumstances. Prompting a dog to stop some activity ("Enough") is balanced by releasing it to engage in another activity. In addition to mixing modules and routines to prevent imbalances, trainers should take care to balance emotional and sensory stimulation. For example, bouts of energetic play should be balanced with periods of inhibitory restraint (e.g., stay and wait training). Experiences causing fearful arousal should be followed by stimulation evoking relaxation or other responses incompatible with fear. Activities resulting in close attachment should be balanced by periods of separation. Assertions of control resulting in submissive behavior are balanced by affectionate

reassurance and opportunities for the dog to compete in constructive ways. Competitive interaction is balanced by engaging the dog in cooperative activities, and so forth. In general, emotionally inhibitory activities are balanced by excitatory ones and vice versa. Organizing behavioral opposites to occur in close association with one another provides a significant source of reinforcement and punishment. For example, releasing the dog from a sit-stay provides a powerful reward for staying, while, conversely, having the come to sit and stay may exert a punitive effect on its willingness to come in the future when called.

Signals and Communication

Dog-training signals use a variety of sensory modalities, with visual, auditory, and tactile signals playing a prominent role. Visual signals include all forms of bodily movement and gesture designed to influence dog behavior in some way. There are both formal and informal visual signals. Formal hand signals are used to inform or reinforce vocal signals issued at a distance. Informal signals are used to communicate an intention or expectation to a dog by directly stimulating some action; for example, running away, crouching down, or clapping the hands can prompt the dog to follow or come. Dogs are also highly responsive to directional gazing and pointing. Apparently, the dog's ability to take instruction by pointing and other gestures (bowing, nodding, and head turning) has been enhanced by selective breeding and learning (McKinley and Sambrook, 2000). Such communication represents a significant form of interspecies exchange between people and dogs (Miklósi et al., 1998). As a result, most dogs can quickly learn to follow directional cuing with minimal practice.

Ideally, training signals should be presented in an orderly way with the least informative signals preceding more informative ones and concluding, if necessary, with directive prompts and physical guidance. Besides being well organized and presented in an orderly manner, these various signals, especially vocal ones, must be well differentiated. The greatest potential for confusion arises when signals are used inconsistently or when they are presented in a manner that makes them difficult to discriminate. To avoid this source of confusion, vocal signals are presented in distinctive tones of voice, depending on their intended purpose.

Vocal signals are used to perform a variety of functions, including conditioned reinforcement, that is, bridging a contingent response with a future reward (e.g., "Good," "Yep," "That's it," and "Yes"), conditioned punishment (e.g., "No," "Eh," "Ack," and "Nah"), and cuing or command (e.g., "Sit"). Vocal praise and directive reprimands (e.g., "Enough," "Stop it," "Leave it," and "Off") serve to produce more general activating or depressing effects on behavior via both conditioned and unconditioned effects of tone of voice on dog behavior. To minimize confusion, vocal signals are spoken in a distinctive and consistent tone. The loudness and tone of vocal signals and the way they are presented are shaped in conformity with the changes that the trainer wishes to make in a dog's behavior. The reprimand is spoken in an assertive tone of voice from the belly; the command is spoken in a clear, normal tone of voice from the chest and throat; and praise is spoken in a lively, friendly, and high-pitched tone of voice from the mouth and throat. The volume of voice is adjusted from soft to harsh for purposes of emphasis. Good communication with the voice depends on keeping these various tones and their intended functions distinct by not saying commands like praise, issuing a reprimand like a command, or delivering a command like a reprimand. Many signals function as establishing operations motivationally shifting behavioral thresholds and making the occurrence of certain classes of behavior more likely while making other classes of behavior less likely. Besides regulating a dog's behavior, tone of voice also serves to modulate the dog's mood and attitude during the training process. The lower and assertive barklike reprimand may trigger innate mechanisms mediating behavioral inhibition and deference (see *Sensory Preparedness* in Volume 1, Chapter 5).

Although dogs are surprisingly clever at deciphering the associative implications of words, they do not seem to understand words

as conceptual constructs. In addition to associative meanings, words signify concepts and relations extending well beyond the reach of a dog's understanding. Concepts are mental representations of related things, and words stand in a symbolic relation to concepts. In addition, words are part of a language system articulated by grammatical rules and syntax to enable us to communicate with one another in meaningful ways. To dogs, words are auditory *images* deriving their *meaning* through associative contiguity with the regular occurrence of some thing, action, or relation in the presence or close association with the vocal signal. According to Hobbes (1651/1994), the dog shares with people an imagining faculty that facilitates such understanding and appreciation of words:

> The imagination that is raised in man (or any other creature endued with the faculty of imagining) by words, or other voluntary signs, is that we generally call understanding, and is common to man and beast. For a dog by custom will understand the call or the rating of his master; and so will many other beasts. That understanding which is peculiar to man is the understanding not only his will, but his conceptions and thoughts, by the sequel and contexture of the names of things into affirmations, negations, and other forms of speech: and of this kind of understanding I shall speak hereafter. (11)

Along with the associative meanings and implications of vocal signals, the tonal variations in which vocal signals are given help to communicate a trainer's emotional state and immediate intentions to a dog. The dog may not appreciate the symbolic or conceptual significance of a word, but it does appear to be extremely sensitive and responsive to the feeling content of vocal signals reflecting the will of the speaker.

The language barrier between people and dogs causes many dog owners to both overestimate and underestimate their dog's capabilities. Some of the difficulty can be attributed to the facility with which we transform experience into mental representations (thoughts and images) that are almost automatically arranged into logical relations and configured into concepts fitted to words. Words give us the ability to represent experience symbolically in terms of causal relations, connecting long-past events (causes) to current or future events (effects). A dog's experience is more temporally confined and limited to the immediate demands of existence surrounding the moment (Roberts, 2002). The stream of life passes by with all its disappointments and adventures, with each moment lived to the fullest or lost. A dog has little time to ruminate on past events or future possibilities, except to the extent that they directly impact on the present moment. Unlike people, dogs lack the symbolic, conceptual, and logical means to connect long-past events and actions with the present moment; that is, they appear to lack an episodic memory. Dogs exist in an ever-present and perpetually becoming *now.*

The dog is remarkable among animals by its willingness to work for affection and approval from a human handler (Kostarczyk, 1991). The dog loves to please, first of all itself, of course; but after some basic training it will work to obtain various social expressions of affection, such as petting, gentle caresses, and praise. Although a brief high-pitched vocal signal like "Good" is preferable for refined training purposes, periodic longer phrases of vocal praise and sweet talk can be extremely useful and beneficial as a means to enhance a dog's incentive to work for social rewards. The vocal bridge "Good" functions as a conditioned reinforcer and exactly refers to some specific behavior, whereas affectionate praise and sweet talk relate more generally to a dog's willingness to work and cooperate. Sweet talk both reassures and encourages dogs. Praise also keeps the training process from becoming too clinical and boring, helping to keep the atmosphere cheerful and fun for dogs and trainers. Gentle, but firm, petting and soft embracing hugs with endearing words are well received by most dogs. As a cynopraxic activity, training is always concerned with ways of maximizing bond and quality-of-life benefits; rather than pursuing the training process with excessively sterile and rigid procedures, cynopraxic training incorporates affectionate means and play whenever possible. Praising and petting is an art that should be given from the heart as a sincere expression of affection and appreciation in response to a dog's behavior and

accomplishments. Nervous finger tickling, fidgeting, and hard shoulder slapping are not usually well received by dogs in training, although many do appear to enjoy a friendly shoulder pat now and then. The key to effective petting is its intention and sincerity. If the heart is not in it, it would be better not to pet the dog—the dog knows the difference. Of course, dogs exhibiting aggression problems should only be handled and touched with appropriate care and precautions.

Attention and Impulse Control

Attention provides a selective interface between the internal and external environment, helping dogs to detect and control events and situations that have motivational significance for them (see *Attention and Learning* in Volume 1, Chapter 7). Attention, impulse (the combined activation of relevant control expectancies and establishing operations), intention, and action are closely linked by a network of classically conditioned predictive associations that inform and motivate instrumental control efforts (see *Basic Postulates, Units, Processes, and Mechanisms* in Chapter 10). When attention falls upon a motivationally significant (salient) object, a control incentive may be aroused, followed by the activation of preparatory responses and intentional movements or orientations in anticipation of overt control efforts (see *Control Incentives and Reinforcement*). Under the influence of appetitive arousal, attention functions may be recruited by control incentives to coordinate instrumental modules and routines leading to gratification (comfort seeking). As the dog commits to a course of action, its attention may be locked or *vectored* on the developing situation and dedicated to the acquisition and processing of real-time information relevant to adjustments conducive to instrumental success. Once launched, highly motivated behavior may only stop after it is consummated (confirmed), fails (disconfirmed), or is interrupted by the evocation of an antagonistic control incentive having a greater motivational significance and priority. In practice, the inhibitory control over impulsive behavior is often accomplished by means of startle or momentary discomfort. The startling event produces a rapid diminution of appetitive arousal while at the same time establishing an incompatible control incentive aimed at escaping the unexpected and dangerous situation (safety seeking). As a result, the appetitive control expectancy is modified to include an element of danger, thereby increasing the dog's responsiveness to inhibitory signals and avoidance when engaged in similar activities in the future.

Although such control efforts are often necessary and expedient for gaining control over certain impulsive behaviors, the routine induction of fear or discomfort to establish control over impulsive behavior risks various adverse side effects, especially in cases where such training is performed incompetently or in the absence of reward-based alternatives. Once a dog is acting on a strong impulse, attempting to interrupt it by means of threats and belated punishment is analogous to grabbing an ox by the tail and whipping it in order to stop it from running away. Of course, a more sensible approach for controlling such a powerful animal is to guide it by means of a rope and nose ring while luring it forward with a clump of fresh hay. Similarly, keeping the dog on a long line or leash and conditioning a strong orienting and attending response in the context of shaping a variety of basic exercises (modules) and skills effectively facilitates enhanced attention and impulse control while reducing the amount of aversive inhibitory training needed to gain reliable off-leash control. The key for effective attention and impulse control is anticipating and capturing the dog's attention in advance of it becoming absorbed by competing environmental sources of reward. Capturing and diverting a dog's attention toward comparable or better sources of reward under the trainer's control is akin to the ox's nose ring, giving the trainer a high degree of leverage for controlling undesirable impulses. In addition to employing preemptive attention-control efforts, the intensive training of orienting and attending behaviors with techniques that produce positive prediction error can significantly improve attention and impulse control and reduce the use of aversive techniques. Atten-

tion control is established by means of both instrumental and classical conditioning mechanisms. For example, a dog's name is first and foremost learned as a discriminative stimulus for controlling the dog's attention; the dog can choose to attend or not when it hears its named called. However, attention (orienting response) is also controlled by a reflexive mechanism. Given a sufficiently salient and unexpected stimulus, such as an unusual sound, a dog—willing or not—will start and orient toward the source of stimulation. Pairing the dog's name with such unconditioned orienting stimuli (e.g., squeak, smooch sounds, clapping, and so forth) and bridging the orienting response with surprise-producing rewards can rapidly enhance the nominal signal's ability to control a dog's attention.

To attend (Latin *attendere,* to heed) and to obey (Latin *oboedire,* to listen) are functionally dependent and intrinsic aspects of the basic training process. Improving a dog's attention and impulse-control abilities by training it to actively listen to and heed human guidance and directives is among the most important core objectives of basic training. When properly understood and performed, training that establishes attention and impulse control serves to form and preserve a shared moment of mutual awareness and consideration (mutual appreciation) while reducing interactive conflict and tension via reward-based training efforts. The cynopraxic process is tantamount to leading the aforementioned ox by means of its nose ring and desire for hay, then letting go of the rope, eventually forgetting about the ox's training, and finally just enjoying the companionship and walk. The mutual exchanges and transactions between the trainer and dog that compose the training process are mediated by the establishment of an attentional nexus bringing the trainer and dog into the same time frame for the sake of mutual benefits derived from their cooperation (interactive harmony).

INTERRUPTING BEHAVIOR

Establishing control over a dog's attention often involves the use of diverters and disrupters to interrupt ongoing behavior. Diverters rely on an element of surprise and attractiveness to turn a dog's attention away from some competing activity. Disrupters, on the other hand, depend on startle and alarm to gain a dog's attention. Interrupting diverters and disrupters may momentarily intensify attention and enhance learning by activating behavioral inhibition and other rapid adjustments via prediction-error signals occurring in response to the detection of a dramatic incongruence or mismatch between what the dog is accustomed to expect and what is happening. With the occurrence of surprise or startle, a brief hesitation or halt in activity may occur while the discrepant information is cognitively and emotionally processed and integrated before the dog's previous activity is resumed or another activity is begun. The effectiveness of diverters and disrupters is influenced by a variety of factors, including previous exposure to the event (see *Latent Inhibition* in Volume 1, Chapter 6), habituation and sensitization, and the presence of other stimuli (e.g., fear-potentiated startle and prepulse inhibition) (see Koch, 1999). In the case of fear-potentiated startle, a previously conditioned fear-eliciting stimulus may serve to potentiate the startle produced by the disrupter. On the other hand, the presence of a conditioned aversive stimulus may decrease the effectiveness of a diverter to attract and hold the dog's attention (see *External Inhibition and Disinhibition* in Volume 1, Chapter 6). An attenuated stimulus (distraction) occurring immediately before the disrupter is delivered may significantly decrease the startle response elicited by the event via prepulse inhibition (see *Prediction and Control Expectancies*). Despite their potential to reward or punish behavior, diverters and disrupters are not conceived of as producing reinforcement or punishment, until the dog produces behavioral efforts aimed at controlling their occurrence (see *Diverters and Disrupters* in Volume 1, Chapter 7). Diverters and disrupters function primarily as generic establishing operations serving to mobilize control incentives and to launch control modules, routines, and modal strategies in accordance with anticipated needs. Although not productive of reinforcement and punishment initially, consequent presentations of diverting

and disrupting stimuli may function as reinforcers or punishers to the extent that a dog is able (reinforcer) or unable (punisher) to predict and control them. Diverters and disrupters play a major role in the control of a wide variety of dog behavior problems (see *Diverters and Disrupters*).

Particular care must be exercised when using diversionary techniques to control behavior problems, since, if improperly used, such procedures can easily result in unintentional reinforcement rather than simply diverting a dog's attention or initiating an incompatible establishing operation. If a dog is repeatedly diverted from some unwanted activity by offering it the opportunity to perform some other more desirable activity, it may gradually learn that the desirable activity can be obtained by engaging in the unwanted behavior. In this case, the diverter is no longer functioning as a diversionary stimulus but has become a positive reinforcer. This risk is always present when a diverter is repeatedly presented in the absence of other training activities, whereby other (DRO), alternative (DRA), or incompatible (DRI) behavior is reinforced following the evocation of a diversionary establishing operation (see *Differential Reinforcement* in Volume 1, Chapter 7). Diverting a dog from one activity to engage in another one usually means that the second activity is motivationally located higher up on the dog's response-priority hierarchy, making it likely that the diversionary activity could function as a positive reinforcer (see *Premack Principle: The Relativity of Reinforcement* in Volume 1, Chapter 7). For example, a dog racing through the house or grabbing personal belongings may be diverted from the activity by picking up a leash, signaling a possible walk. If a walk follows regularly at such times, the dog may learn to control the opportunity to go for a walk by engaging in rambunctious behavior. In this case, the lower-priority behavior (racing through the house) is instrumental in obtaining the higher-priority behavior (going for a walk). For owners of such dogs, it may not be clear to them that the pattern of picking up the leash is not only serving to stop the unwanted behavior but is also inadvertently helping to maintain it. In fact, an owner may be quite gratified by the momentary success achieved by getting the leash whenever the dog appears out of control. In sum, the outcome is a *behavioral trap* in which short-term control is achieved at the expense of increased undesirable future behavior (Tortora, 1980).

Bribes and threats may be confused with diverters and disrupters, but function in very different and problematic ways. Dogs are commonly bribed after they have refused to come when called. Although the offer of a food bribe may cause a resistant dog to come, the bribe also directly reinforces the refusal behavior. As the result of repeated bribery, the refusal behavior may actually become stronger than the dog's interest in obtaining the offered food bribe, causing the owner to produce something even better to gain the dog's resistant compliance. Improving the bribe serves only to strengthen the refusal behavior further and so on, with the *bribe trap* progressively leading to a deterioration in the dog's willingness to come when called. Unenforceable threats following misbehavior or refusal to obey can be equally problematic. Under the influence of empty or inconsistently enforced threats, a dog's unwanted behavior may increase as it finds that the threatened consequence is not forthcoming, causing it to experience a significant amount of relief by evading the owner's punitive efforts successfully. Furthermore, in the case of the *threat trap,* because some percentage of threats are effective, the owner's threatening behavior is intermittently reinforced and may persist despite a progressive deterioration of overall control. Dogs exposed to such treatment quickly learn that staying away at a safe distance insulates them against any real consequences associated with threats. Consequently, rather than helping to suppress unwanted behavior, repeated and ineffectual threats may serve only to encourage a dog to misbehave at a safe distance out of the owner's reach. In an effort to counteract the dog's defensive ploy, the impatient owner may complicate matters further by enticing the dog to come within his or her reach before grabbing it and delivering a dose of belated and self-righteous punishment. Although the owner may feel privately vindicated by a belief that justice had been served or some such

hokum, the only thing that a dog is likely to learn from such abusive treatment is to be more wary and difficult to catch in the future. In addition, such acts of calculated deception may rapidly train a dog to view the owner and others with distrust, thereby potentially setting the stage for more serious adjustment problems later.

TRAINING AND PLAY

In the process of describing the procedures and techniques of basic training, it is easy to lose sight of some of the subtle nuances and flavor, the sundry incidental activities and diversions (e.g., spontaneous playfulness and affectionate interaction), the rhythm and dancelike quality of the interaction between the trainer and dog, and the general presence of fun and excitement associated with training a dog. In fact, nothing is more important to successful training than play. Although food is a tremendously useful reward, excessive reliance on food should be avoided, and other sources of reinforcement should be identified and used to support training objectives, with the goal of actualizing the dog's whole emotional and behavioral potential. In addition to an appetite for food, dogs exhibit a wide range of other social and physical needs that seek gratification, but, most importantly, they need to play and they enjoy playing with people. Consequently, whenever possible, training objectives should be organized around play incentives. Playing with dogs makes them more flexible and willing to open their behavioral repertoire creative experimentation and change. In the context of play, social limits and rules are much more readily accepted and incorporated into everyday interaction. Play makes change and adaptation easier and more durable, seeming to promote a sense of joyful harmony and trust between people and dogs (The *Cynopraxic Trainer's Attitude* in Volume 2, Chapter 10). In the case of serious behavior problems, play often offers a valuable behavior-therapy modality for accessing and modulating affected emotional command systems (see *Modulatory and Unifying Effects of Play* in Chapter 6).

By means of modal play and exploratory activities, dogs interact with and adapt to the social and physical environment. In essence, dogs learn about people and their surroundings by playing and exploring (Trumler, 1973). In the context of instrumental control efforts, active modal play and exploratory strategies help to shape and entrain control modules, routines, and projects into patterns of instrumental behavior via the discovery of outcomes conducive to surprise (reward) and the avoidance of outcomes producing disappointment. Active modal strategies are activated (rewarded) or depressed (punished) by positive and negative prediction errors, respectively (see *Prediction and Control Expectancies*). Play appears to be particularly sensitive to the effects of positive prediction error, making it a potent source of reward and mood enhancement. The canine disposition to play and explore endows the dog with a high degree of curiosity and capacity for producing reward derived from the discovery of stimuli evoking positive prediction error and surprise. In addition to mediating reward, play appears to perform a special modal balancing and integrating function in relation to emotional command systems (see *Play and Drive* in Chapter 10). A lack of playfulness or an inability to sustain playful interaction is a reliable indicator of emotional imbalance, degraded mood, or disease. Given the social and quality-of-life objectives of cynopraxic training, it is natural that play should figure centrally in the process of behavioral change and adjustment (see *Fair Play and the Golden Rule* in Chapter 10). During playful interaction, both the dog and the trainer learn the value of compromise and cooperation; without mutual compromise and cooperation, playful interaction cannot be sustained. In contrast, time-out (i.e., loss of social contact and reward) has an opposite effect on modal activity and serves to mediate passive module strategies via disappointment and decreased reward incentive (de-arousal).

A spirit of affectionate playfulness should inform the training process. Training sessions frequently, but not always, start off with play, but formal sessions should always end on a playful note. Periodic bouts of play are interspersed throughout the session, bringing

trained modules and routines under the motivational influence of playful incentives. Training a dog to control playful impulses by turning them on and off again in the process of rewarding compliant behavior provides a powerful means to improve impulse control. As Hediger (1955/1968) once aptly noted, "Good training is disciplined play" (139). Spontaneity does not arise out of chaos, but is born under the nurturing influence of order, discipline, and play. As trained behavior becomes reliable (i.e., well predicted and controlled), first through reward training using social and appetitive reinforcers and then directive training conducive to enhanced competence, relaxation, and safety, further refinement and integration are achieved via the unifying influence of ludic incentives and play rewards. Play rewards gradually transform the significance of trained behavior via associative processes, whereby trained responses become progressively linked with playful affects, ludic incentives, and qualities (e.g., spontaneity and joy). Under the liberating influence of play rewards, trained behavior becomes more responsive to reorganization and generalization. Play makes the training process more creative for trainers and makes work more fun for dogs. Just as training sessions are started and concluded with play, play is both the means and the end of cynopraxic therapy.

The Training Space

Setting appropriate social boundaries and limits is an important foundation for all training activities. All dogs must learn to respect three basic boundaries at the outset of training: limits on jumping up, limits on biting on hands and clothing, and limits on pulling against the leash. In most cases, these behaviors are not entirely suppressed but redirected or modified into more acceptable forms. Although spontaneous jumping up is not permitted, dogs may be trained and permitted to jump up on cue. Similarly, while biting on hands and clothing is discouraged, biting on tug toys is encouraged with play. Since both jumping up and tug games are highly enjoyable activities for dogs, they can be invited to jump up or given opportunities to play tug as a reward. Similarly, from an early age, puppies should be discouraged from pulling by various means. Such boundaries are set by first causing the dog to passively defer and then to actively follow the trainer's rules of interaction, defining when it can jump up or bite. Besides learning to relinquish control and to desist from competitive challenges, the establishment of social boundaries enhances a dog's attention and impulse-control abilities. The limits and training set around jumping up, biting, and pulling form a training space within which reward-based training activities can be carried out. Without the establishment of a viable training space, training activities may be continuously frustrated by intrusive social excesses and oppositional behavior.

Instrumental Reward and Punishment

Just as objects acquire the appearance of form and solidity as the result of the interplay of light and dark on their surface, behavior is shaped through the complementary influences of reward and punishment. Practically speaking, behavior is formed and structured by systematically arranging reward and punishment to occur in ways that produce controllable behavioral changes consistent with immediate (proximal) and remote (distal) training objectives. The conventional definitions of reinforcement by reward and suppression by punishment stress the complementary effects that these events have on the frequency or probability of behavior as consequences, but without much reference to the emotional or cognitive processes mediating the observed effects (see *Basic Concepts and Principles of Instrumental Learning* in Volume 1, Chapter 7). This general characterization of instrumental learning by reward and punishment, founded on Thorndike's law of effect, appears to be overly simplistic and theoretically inadequate for capturing the complex and organized nature of adaptive learning processes. The conventional view neglects critical molar and modal aspects of learning and behavioral organization, perhaps as the result of an excessively myopic emphasis on molecular relations

between consequent events and isolated responses. Of particular interest from the perspective of cynopraxic behavior therapy and training are the acquired molar relations operating under the organizing influences of emotional and cognitive processes.

Control Incentives and Reinforcement

The effects of reinforcement and punishment are quantified by reference to the differential changes that the events have on response probability or frequency. However, defining reinforcement and punishment in terms of probability is rather circular and inadequate for several reasons (see *Reinforcement and the Notion of Probability* in Volume 1, Chapter 7). Alternatively, reinforcement and punishment can be viewed from the perspective of a control incentive and function. According to the control-incentive theory, behavior that enhances an animal's control over significant events produces reinforcement whereas behavior that impairs control efforts results in punishment. Changes in the frequency or probability of the reinforced or punished behavior are secondary to its success or failure to improve an animal's ability to control the environmental event prompting action. The establishment and optimization of control over attractive or aversive events appears to be an important aspect of reinforcement and punishment for dogs. Dogs work to optimize their control over attractive events by obtaining or maintaining their availability; similarly, they work to escape, reduce, or avoid aversive ones. Normally, when a dog acts, it does so with the intent of producing some specific effect on the environment; that is, instrumental behavior is purposive and shaped by the accumulated successes or failures that such efforts afford with respect to the control of significant events. To the extent that these efforts are successful, they are reinforced and integrated into a dog's behavioral repertoire, whereas efforts that fail to control attractive or aversive events adequately are punished by loss or discomfort and are gradually modified or removed from a dog's behavioral repertoire, at least in those situations where the actions have failed to enhance control efforts. In short, according to the control-incentive theory, reinforcement occurs when purposive efforts succeed in enhancing a dog's control over some motivationally significant event, whereas punishment occurs when such purposive efforts fail to make a difference or make matters worse; that is, they result in a lack or loss of control.

Premack's interpretation of reinforcement and punishment is consistent with a control-incentive analysis (see *Premack Principle: The Relativity of Reinforcement* in Volume 1, Chapter 7). According to Premack, instrumental behavior is reinforced or punished by the occurrence of other behavior. The reward value of any particular behavior is determined by its probability of occurrence relative to other behaviors operating under similar motivational and environmental circumstances. Therefore, at any given moment, an animal's behavioral repertoire is distributed along a hierarchic continuum from behaviors that are least likely to behaviors that are most likely. Behaviors that are more likely tend to reinforce behaviors that are less likely, whereas behaviors that are less likely tend to punish behaviors that are more likely. In short, instrumental behavior is reinforced by other behavior occurring at a higher probability. Premack's response-probability hierarchy is really a control-incentive index. Obviously, responses of the highest probability are precisely those that would most likely lead to enhanced control over some immediate and motivationally significant event, whereas responses with low probability and reinforcement value are precisely those actions with the least likelihood of establishing control or those that may actually impair control efforts. Low-probability responses are potentially punitive, not because they are assigned a low probability or intrinsic hedonic value, but because they do not directly serve the animal's immediate control interests. High-probability responses are those that are most relevant or likely to succeed with respect to the control of motivationally significant events, whereas low-probability responses are those that are most irrelevant or likely to fail.

Although control incentives are functionally significant with regard to reinforcement and punishment, the gratification of a control incentive is not sufficient to explain the

organizing effects of learning. In addition to control incentives, various predictive influences are at work. In an important sense, instrumental control incentives appear to emerge in the context of classical conditioning. The predictive information produced by associative learning provides a framework for instrumental control efforts. Classical conditioning provides predictive information about the occurrence of significant events and prepares a dog motivationally for them, whereas instrumental learning is concerned with optimizing a dog's ability to control the events when they occur. The orderly nature of learning suggests that it occurs within the context of prediction-control expectancies. As argued in *Prediction-Control Expectancies and Adaptation* in Volume 1, Chapter 7, reinforcement and punishment are not so much about the effects of arbitrary attractive and aversive events increasing or decreasing the future probability of some isolated response, but rather the result of the confirmation or disconfirmation of instrumental control expectancies. Control expectancies are the encoded results of past instrumental efforts to exploit or avoid attractive or aversive events. Classical and instrumental learning activities share a common organizing function, viz., to make the environment more predictable, controllable and, consequently, more comfortable and safe.

Classical Conditioning, Prediction, and Reward

Successful control over significant events depends on the accumulation of predictive information concerning their occurrence. Classical conditioning not only provides predictive information about the occurrence of attractive and aversive events, it also establishes a complex network of predictive contingency relations between antecedent and consequent events that guides instrumental control efforts (see *Relations Between the Signal, Response, and Outcome* in Volume 1, Chapter 7). In addition to providing predictive information that is incorporated into instrumental control expectancies, classical conditioning significantly influences instrumental behavior via excitatory and inhibitory emotional influences (Rescorla and Solomon, 1967; Dickinson and Pearce, 1977). At the level of organizing functions, the conventional distinctions between classical and instrumental learning begin to dissolve. The successful control of significant events depends on the acquisition of accurate predictions regarding the details of their occurrence, size, and quality. Similarly, adequate prediction depends on feedback derived from instrumental control efforts.

Refinement of instrumental control efforts depends on information obtained from conditioned stimuli, especially those stimuli that are relevant to control efforts. In the process of training, for example, bridging stimuli (conditioned reinforcers) play an important role in the acquisition and maintenance of learned behavior. In addition to evoking various conditioned appetitive and emotional responses, bridging stimuli are informative about the size, type, and frequency of the pending attractive or aversive event. In fact, the ability of bridging stimuli to control and modify behavior appears to depend on their information value (Egger and Miller, 1962). Optimal bridging effects occur when new and surprising information is obtained about the occurrence of rewarding stimuli. The moment of reward is not when a dog ingests food or when it receives affectionate attention and petting, but, more precisely, reward occurs at the moment a dog detects some new bit of information that enhances its control over such motivationally significant events. Reward and punishment appear to depend on the detection of a discrepancy between what a dog expects to occur and what actually occurs: reward occurs when the outcome is better (more attractive) than expected (surprise), whereas punishment occurs when the outcome is worse (less attractive) than expected (disappointment). A similar relationship is obtained in the case of aversive events: reward occurs when the expected outcome is better (less aversive) than expected (relief), whereas punishment occurs when the outcome is worse (more aversive) than expected (startle). As the result of prediction discrepancies, conditioned reinforcers undergo excitatory or inhibitory changes in accordance with the Rescorla-Wagner model; that is, only

when the conditioned stimulus (CS) either underpredicts (excitatory) or overpredicts (inhibitory) the unconditioned stimulus (US) does additional learning take place (see A*ssumptions Derived from the Rescorla-Wagner Model* in Volume 1, Chapter 6). Three possible effects on the associative strength of the bridging stimulus occur in association with attractive and aversive outcomes:

1. If the outcome is more attractive or aversive than expected (surprise or startle), then excitatory conditioning occurs—the associative strength of the conditioned reinforcer is strengthened.
2. If the outcome is less attractive or aversive than expected (disappointment or relief), then inhibitory conditioning follows—the associative strength of the conditioned reinforcer is weakened.
3. If the outcome is exactly as expected (comfort and safety), then no additional learning occurs (the prediction is verified)—the associative strength of the conditioned reinforcer is unchanged.

Studies focusing on the response of dopamine (DA) neurons to the presentation of signals with varying temporal and predictive relations to rewarding stimuli indicate that the activation (reward) or depression (punishment) of reward-mediating DA neurons depends on the detection of discrepancies between what an animal expects and what actually occurs (Waelti et al., 2001). DA reward signals are generated in association with positive prediction errors (the attractive outcome is better than expected), whereas punitive signals are produced in association with negative prediction errors (the attractive outcome is worse than expected) (Schultz, 1998):

> All responses to rewards and reward-producing stimuli depend on event predictability. Dopamine neurons are activated by rewarding events that are better than predicted, remain uninfluenced by events that are as good as predicted, and are depressed by events that are worse than predicted. (1)

In essence, the collection of DA neurons localized in the ventral tegmental area generate teaching signals in response to the detection of prediction errors, thereby facilitating improved adaptation and organized behavior via an incentive to explore, experiment, and discover. These various behavioral and neurobiological findings complement the behavioral findings of Egger and Miller (1963) and lend support to their hypothesis that "reinforcement occurs primarily at the point at which new information is delivered" (132). As such, learning appears to depend on expectancy errors that variably lead to surprise and disappointment—errorless learning is an oxymoron. Outcomes that are well predicted and expected do not support additional learning, even though the attractive outcome consistently follows the learned behavior—a fully predicted reward appears to block additional learning (plateau). Such outcomes serve to verify the control expectancy, gratify the control incentive, abolish the establishing operation, and contribute to feelings of comfort and safety, but they do not produce reward.

As instrumental behavior becomes stable under the influence of repeated bridging and reinforcement, DA release shifts to the earliest predictor of impending reinforcement, viz., the bridging stimulus (Schultz, 1998) (Figure 1.2). DA activation via bridging stimuli exhibits a preference for stimuli with a clear onset and alerting quality. Also, DA neurons are exclusively sensitive to the onset of the bridging stimulus and are unresponsive to its offset, even if the offset coincides with the delivery of the rewarding stimulus (Schultz, 1998). These findings suggest that the bridging stimulus should be brief and crisp and have an alerting quality, helping to explain the bridging efficacy of brief high-pitched vocal sounds, squeakers, whistles, and clickers. The conditioned effect of bridging stimuli may be mediated via efferent pathways originating in the amygdala (Hassani et al., 2001). The lateral nucleus of the amygdala contains neurons that are highly sensitive to acoustical stimulation, which play an important role in the detection of auditory conditioned stimuli. In addition to receiving afferent acoustical signals via the thalamus and sensory cortex, the amygdala forms strong efferent connections with DA neurons in the

ventral tegmental area (Schultz, 1998), lending some credibility to the hypothesis that the amygdala may be involved in the process of conditioned reinforcement. In any case, noradrenergic pathways also probably play a role, since norepinephrine (NE)-producing neurons originating in the locus coeruleus exert a potent excitatory effect on numerous forebrain areas mediating orienting and alerting responses to conditioned appetitive and aversive stimuli, as well as novel or startling ones (see *Reticular Formation* in Volume 1, Chapter 3). As in the case of DA neurons, NE neurons are responsive to changes associated with learning. Whereas DA neurons appear to be responsive to the appetitive and hedonic salience of significant events, NE neurons are responsive to their attention-grabbing aspects (Schultz, 1998). Conditioned reinforcement appears to involve a coordinated process involving both NE and DA circuits, with the former mediating alert and orientation to the bridging stimulus and the latter assessing its appetitive and hedonic significance. In addition to mediating orienting responses and selective attention, NE circuits appear to play an important role in

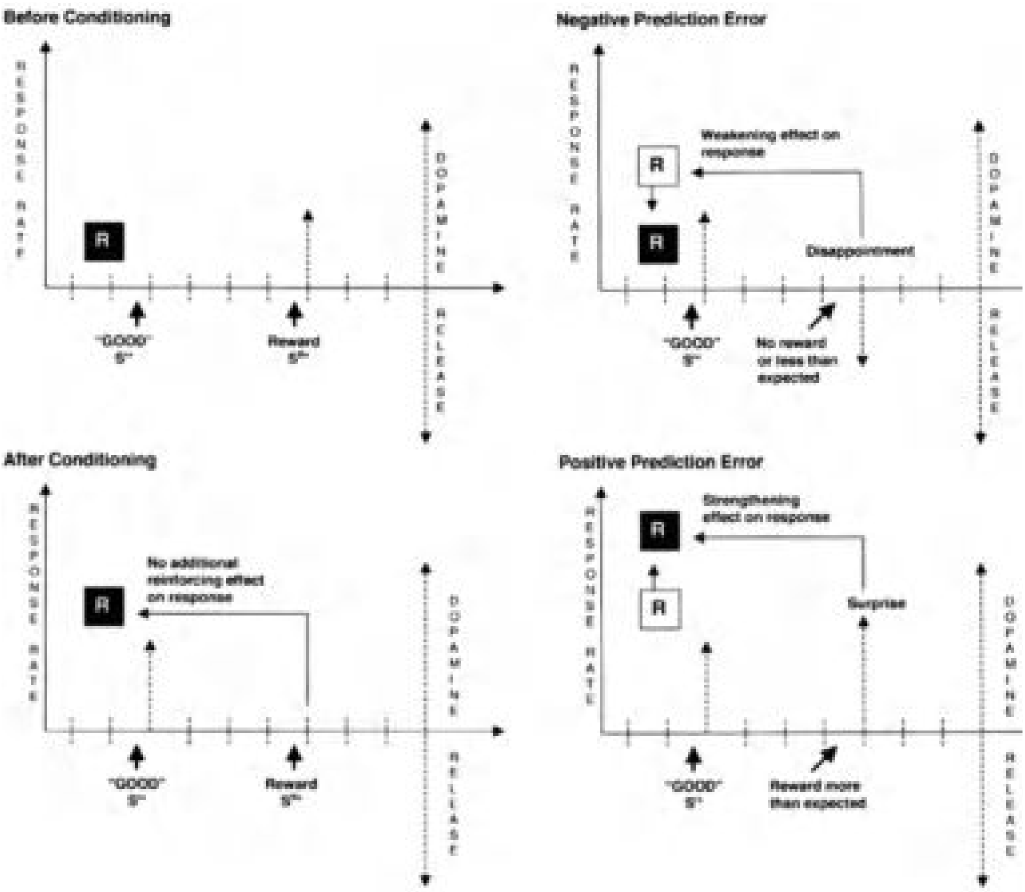

FIG. 1.2. Prior to conditioning, the vocal signal "Good" (S^{R+}) fails to provide conditioned reinforcement, as indicated by the absence of dopamine reward activity. After conditioning, however, dopamine release shifts toward the occurrence of the conditioned reinforcer and away from the predicted reward (S^{R+}). The well-predicted reward loses its capacity to activate the release of dopamine. Without a prediction error, additional learning does not appear to occur.

more flexible scanning activities (Aston-Jones et al., 1999).

Prediction and Control Expectancies

Learning appears to proceed as the result of the acquisition and refinement of prediction-control expectancies, necessitating the postulation of a hypothetical expectancy-comparator mechanism, whereby what a dog expects to occur is compared with what actually occurs (see *Neural Comparator Systems* in Chapter 10). Numerous comparator circuits sensitive to prediction error are distributed throughout the brain, mediating a variety of neural and behavioral adjustments in response to changing moment-to-moment circumstances (Schultz and Dickinson, 2000). These specialized comparator circuits appear to communicate together and orchestrate complex adaptive functions, including the detection of prediction errors conducive to reward and punishment. Prediction-error signals resulting in reward and punishment are produced when what the dog anticipates to occur as the result of an action (control module) and conditioned reinforcement turns out to be better or worse than expected. Such positive and negative prediction errors differentially produce reward or punishment by activating or depressing dopamine activity.

According to the expectancy-comparator model, predictions are processed by a complex series of feedback loops that serve to confirm or disconfirm expectancies, process error signals, calibrate appetitive and emotional establishing operations, and adjust behavioral output to control target events more effectively. In the process of confirming instrumental control expectancies, the detection of prediction discrepancies results in four possible effects:

1. Attractive outcomes that occur earlier than anticipated or are better than expected serve to produce positive prediction errors, surprise, and reward signals.
2. Attractive outcomes that are omitted or turn out to be worse than expected serve to produce negative prediction errors, disappointment, and punitive signals.
3. Aversive outcomes that are omitted or are better (less painful or frightening) than expected serve to produce positive prediction errors, relief, and reward signals.
4. Aversive outcomes that occur sooner than anticipated or are worse (more painful or frightening) than expected serve to produce negative prediction errors, startle, and punitive signals.

The practical implications of these findings are significant. Deliberately arranging reward outcomes to produce positive prediction error serves to make training efforts more efficient and effective, helping to avoid plateaus and enhancing performance reliability and quality (e.g., speed and enthusiasm), even in the presence of highly attractive distractions. However, simply varying rewards randomly is not conducive to positive prediction error and the generation of DA reward signals. Prediction discrepancies and errors can be detected only against a backdrop of an already established pattern of highly predictable outcomes. Consequently, the first step is to provide the dog with a highly predictable and controllable pattern of reinforcement, thereby establishing a standard expectancy against which deviations can be detected and compared. The destructive behavioral effects associated with unpredictable and uncontrollable social interaction may be due in part to a failure to develop a standard against which to judge outcomes and detect prediction discrepancies conducive to reward activation. Typically, variables conducive to prediction error are arranged to occur as trained responses approach or reach plateaus. Plateaus in the training process signal the need for additional reward, and the way to achieve that effect is not by providing bigger and better rewards, but by introducing prediction-error contingencies, that is, vary the size, type, frequency, and timing of the reinforcing outcome. Outcomes can be varied in a variety of ways while training the dog. During recall training, for example, as the dog turns to come in response to its name or a relevant orienting stimulus (e.g., hand clap or lip smooch), the trainer flicks the right hand out to the side with fingers wrapped in a fist around the reward. As the dog touches the closed hand with its nose, the trainer says

"Good" and the reveals the contents. Alternatively, a clicker can be closely paired with the opening of the hand (see *Introductory Lessons*). As the dog learns to come and touch the hand, the concealed reward is varied in different ways. In addition to varying the size and type of reward, the length of time the dog must wait before the hand is opened is also varied from an immediate presentation to a 3-second delay. Another method of varying rewards involves sustained reinforcement. In this case, instead of altering the amount and type of the reward and giving it to the dog all at once, it is given to the dog over a period in a piecemeal fashion. For example, after the dog comes and sits, a treat or two is broken up into a dozen small pieces and fed one piece at a time over the course of 15 to 20 seconds. Sustained-reinforcement techniques can be particularly effective in dogs with attention problems. Rewards are presented in such a way that the dog cannot predict how much food it will receive as a reward or how long it must wait. Mixed into this pattern are other types of food rewards (e.g., kibble, various meats, biscuit pieces, cheese, jerky, cereals, and soft treats). Varying the amount and type of reward appears to maximize the effect of reinforcement, causing dogs to work harder and rendering the learned behavior more resistant to extinction. Because the reward varies in size, type, frequency, and timing of presentation, the dog is alternately affected by surprise and disappointment. When reward (surprise) and punishment (disappointment) are presented in a balanced proportion, a prediction dissonance and control incentive based on hope is produced. Prediction-error contingencies that provide more reward (positive prediction error) than punishment tend to produce prediction-dissonance effects conducive to elation and increased active modal activity, whereas contingencies that limit positive prediction error tend to produce behavioral plateaus and ruts, boredom, and despair. Finally, poorly predicted contingencies that involve uncontrollable aversive stimuli or outcomes producing more punishment (negative prediction error) than reward are prone to produce maladaptive prediction-dissonance effects and neurotic passive modal activity, with increased anxiety and frustration (behavioral stress), depression, and irritability.

A comparator mechanism associated with the septohippocampal system (SHS) appears to respond to prediction discrepancies related to novelty and startle. Prediction-error signals originating in the SHS are believed to activate a neural network mediating startle and behavioral inhibition, causing the animal to "stop, look, and listen, and get ready for action" (Gray, 1991:114) (see *Learning and the Septohippocampal System* in Volume 1, Chapter 3). The momentary pause in activity produced by novelty and startle may be the result of a sensorimotor priority given to unusual or unexpected events. Novelty and startle appear to activate increased emotional and cognitive processing, apparently with the goal of assessing the significance of unusual events and adjusting behavioral output accordingly; that is, novelty and startle are received and interpreted in terms of new information. Consistent with such a information-processing function, attenuated stimuli occurring immediately before the startling event appear to perform an automatic sensorimotor gating function (prepulse inhibition), whereby excessive or insignificant stimuli occurring at the moment of stimulation are barred from cognitive and emotional processing in order to prevent overload and help to ensure that only the most relevant stimuli present in the situation are focused upon (see Koch, 1999). The gating function associated with prepulse inhibition suggests the possibility that subtle signals immediately preceding a startling event may be preferentially associated with startle—a phenomenon confirmed by many common dog-training applications of startle conditioning. In addition to enhancing startle-conditioning effects and learning, an attenuated vocal, auditory, or olfactory signal presented immediately before a startling event appears to reduce the magnitude of the startle response significantly. Interestingly, the absence or lack of prepulse inhibition appears to be a marker associated with a variety of psychiatric disorders (Braff et al., 2001).

Gray (1991) has proposed that behavior is regulated by three focal neural systems: a behavioral approach system (BAS), a behavioral inhibition system (BIS), and a flight-fear system

(FFS). The BAS is activated by stimuli associated with appetitive arousal, reward, and the cessation of punishment, whereas the BIS is activated by unfamiliar stimuli (novelty), startle, and conditioned stimuli associated with aversive events and punishment (loss of reward). The FFS is activated by unconditioned aversive stimulation and nonreward (i.e., loss of safety and comfort) mediating escape behavior and defensive aggression. In addition to mediating rapid and disruptive startle, hesitation, or avoidance in response to startle and novelty, the BIS is activated by conditioned aversive stimuli and biologically prepared fear stimuli, loss of reward (negative prediction errors), or the disconfirmation of control expectancies. The BAS, on the other hand, is activated by conditioned and unconditioned stimuli eliciting appetitive arousal (establishing operations) and by signals of reward and the absence of punishment (positive prediction errors). Whereas the activation of the BIS by novelty/startle or loss of reward promotes increased arousal, scanning and vigilance, hesitation, and waiting, the activation of the BAS via surprise-dependent reward intensifies attention and interest, and promotes fearless seeking, searching, and exploratory activities. The BAS operates under the modulating influence of dopaminergic pathways in close association with the activation of species-typical motor programs. Under the influence of excessive BAS activation and imbalance, a dog may be made more vulnerable to compulsive-impulsive spectrum disorders. The BIS, on the other hand, appears to be under the modulating influences of noradrenergic and serotonergic pathways (anxiety-depression spectrum). Excessive activation of the BIS is associated with anxiety-depression spectrum disorders. The BAS and BIS are the rough neural correlates of active and passive modal activities and strategies.

Instrumental Control Modules and Modal Strategies

According to cynopraxic training theory, control expectancies are closely coordinated with establishing operations and adaptive modal strategies. Establishing operations are under the regulation of classical conditioning and mediate associative and motivational linkages between control expectancies and emotional command systems. Functionally speaking, establishing operations calibrate appetitive and emotional arousal in accordance with predictive information derived from instrumental control efforts. In effect, the establishing operation mediates a precise motivational state that defines in advance the sort of instrumental output needed to obtain gratification, that is, produce outcomes conducive to comfort or safety. Collectively, instrumental control incentives, appetitive and emotional establishing operations, prediction and control expectancies, and instrumental actions are referred to as control expectancy modules (control modules). Control modules, routines (linked modules and skills), and goal-directed projects operate within the context of active and passive modal strategies to form patterns of adaptive behavior. Control modules and adaptive modal strategies are postulated as the basic units of behavioral organization. Modal activities are general classes of motivated behavior consisting of active strategies (exploring, seeking, playing, searching, experimenting) and passive strategies (checking, waiting, hesitating, deferring, delaying, worrying), roughly corresponding to Gray's BAS and BIS. Control modules and routines operate in close association with modal strategies. Positive and negative prediction errors produced by the operation of control modules and routines have a differential activating or depressing influence on behavior and mood, mediating the expression of active and passive modal strategies. The various immediate and cumulative emotional and mood effects associated with positive and negative prediction error are referred to as positive and negative dissonance.

Active modal strategies develop in association with control modules and routines in the process of optimizing control efforts over aversive and attractive events. Active modal strategies organize the performance of control modules and routines into patterns of behavior that increase the likelihood of producing positive prediction errors, that is, set the occasion for surprise, discovery, and reward. Control incentives involving attractive and aversive outcomes entrain control modules and routines into patterns of modal searching, exploring, experimenting, adventure, risk taking, and daring. Active modal strategies are supported by reward (that is, better-than-expected outcomes)

produced in the process of exploiting appetitive resources or controlling dangerous situations. Passive modal strategies are closely associated with the operation of well-established and orderly control modules and routines, representing the conservative, preservative, careful, and risk-avoidant patterns of organized behavior. Passive modal strategies are primarily involved in the detection and avoidance of negative prediction error (disappointment) and punishment.

Passive modal strategies develop in situations where active modal strategies fail (i.e., produce punishment and loss of reward). Under adverse circumstances, punishment may educe incompatible passive modal strategies (e.g., waiting, hesitating, deferring, delaying) aimed at avoiding negative prediction error and punishment. Although passive modal strategies are organized to preserve security (comfort and safety), they do so at a heavy potential cost that may, if performed in excess or to the exclusion of active modal success, ultimately result in progressive disorder and insecurity. Excessive passive modal activity is associated with increased worry and hypervigilance, the gradual loss of responsiveness to reward (dissatisfaction and pessimism), and increasing vulnerability to aversive arousal and emotional tone (anxiety, depression, and irritability). Active modal strategies, on the other hand, tend to pattern control modules and routines toward increasing behavioral variability and output via the search and discovery of positive prediction error (surprise and reward). In contrast to the aversive emotional tone (anxiety and depression) and inhibition of behavioral output associated with passive modal strategies, active modal strategies promote elation, excitement, enthusiasm, and diversification of behavior. However, under situations where active modal strategies operate in relative isolation from the order-enhancing influence of passive modal strategies, various imbalances involving impulsiveness, overactivity, attention deficits, loss of control, and behavioral disorganization may ensue. When functioning together harmoniously and operating under the prediction dissonance of hope, active and passive modal strategies produce a behavioral organization consisting of a balance of order and variability (see *Organizational Order and Variability*). A clarification and elaboration of these various distinctions and their implications for dog behavior therapy and training are provided in Chapter 10.

Establishing Operations

An overarching and paramount psychological need is the optimization of predictive control over the local environment via learning and behavioral adaptation. The attainment of such goals presumes the existence of orderly and stable environmental circumstances. Dogs are motivationally affected by a variety of transient conditioned and unconditioned establishing operations conducive to enhanced prediction and control (see *Antecedent Control: Establishing Operations and Discriminative Stimuli* in Volume 1, Chapter 7). An establishing operation consists of any activity, event, or condition that renders a reward more effective. In addition to enhancing the motivational salience and effectiveness of instrumental rewards, an establishing operation sets the occasion for the occurrence of behaviors previously rewarded under its motivational influence. For example, food deprivation is an appetitive establishing operation that significantly enhances the reward value of food while at the same time encouraging dogs to offer behavior that has been rewarded previously with food. Conversely, activities, events, or conditions that reduce the effectiveness of a reward and decrease the occurrence of responses previously reinforced by it are referred to as abolishing operations (Michael, 2000). For example, satiation has an opposite effect on the value of food as a reward; that is, feeding the dog before training reduces the appetitive value of food and decreases the occurrence of behaviors that have been rewarded with food in the past. Identifying and using establishing and abolishing operations are important aspects of behavior assessment and problem solving (McGill, 1999; Iwata et al., 2000).

At the cognitive-emotional level of organization, establishing operations are postulated as performing the role of coordinating motivational arousal with instrumental behavioral adjustments via a loop of classically conditioned prediction expectancies (see *Adaptation, Prediction Error, and Distress* in Chapter

10). Establishing operations calibrate appetitive and emotional arousal to match behavioral output in terms of ongoing and anticipated situational change. The instrumental control expectancy defines in advance the sort of behavior needed to gratify the motivational state produced by the establishing operation. As such, establishing operations function as interfacing conduits between control expectancies and emotional command systems. Establishing operations are modulated by prediction-error signals coded in the process of confirming or disconfirming control expectancies. Both control expectancies and establishing operations are adjusted and refined in response to reward and punishment signals, thereby enabling dogs to better predict and exploit or avoid the detected discrepancy in the future. Active (e.g., seeking) and passive (e.g., waiting) modal strategies are highly sensitive to the activating and depressing effects of positive and negative prediction errors. Active modal strategies, including social and environmental exploring, searching, experimenting, testing, and so forth are dedicated to the search for positive prediction errors and the avoidance of negative ones. The enhanced order and security provided by instrumental control modules, routines, and patterns are the accumulated results of useful discoveries produced in cooperation with active and passive modal strategies. Modal strategies are not functionally independent of control expectancy modules, but rather depend on prediction errors arising in the process of confirming or disconfirming them. Whereas control modules and routines produce order conducive to survival and security (comfort and safety), active modal strategies promote variability, discovery, and risk taking. Passive modal strategies are likely to occur primarily under conditions of order and where active modal strategies are likely to produce loss of reward or punishment (see *Drive-related Modal Activity and Strategies* in Chapter 10).

Daily activities provide numerous opportunities to exploit establishing operations conducive to increased instrumental output and reward. Using these transient moments of heightened motivation is a central aspect to ICT. For example, going for a walk is usually a highly valued activity for most dogs. Occasions anticipating a walk trigger significant anticipatory arousal, frenetic pacing, jumping up, and barking. The establishing operations associated with getting ready to go for a walk motivationally set the occasion for a variety of undesirable behaviors that are reinforced before a dog is let outside. If, instead of allowing the dog to engage in undesirable behavior at such times, the trainer requires that the dog perform a balanced cycle of tasks before leaving the house, the behaviors involved will undergo significant reinforcement and change over time in association with the opportunity to go for a walk. Another valuable establishing operation occurs as the result of separation. Following a long separation, a dog's interest in social attention and contact is significantly enhanced. The resulting social establishing operation can be used to promote a variety of training objectives. Social rewards can be used effectively at such times to reinforce attention and impulse control, as well as to strengthen the dog's willingness to come when called and other basic exercises. Another everyday opportunity for exploiting motivation conducive to training occurs in association with feeding times. Training that uses food reinforcement is enhanced by taking advantage of appetitive establishing operations associated with the expectation of a pending meal.

Despite the usefulness of social and appetitive establishing operations, the ultimate motivational operation for dog-training purposes is play (see *Modulatory and Unifying Effects of Play* in Chapter 6). Ludic establishing operations are resistant to satiation (abolishing operations) and conducive to the mood-enhancing effects of reward. For example, when catching a flying disk or chasing an out-of-round rubber toy, a tremendous amount of variety occurs in a dog's movements and the effects produced by them. With every chase and catch, deviations from the standard expectancy occur that are conducive to prediction error: air turbulence may cause the disk to turn up or down, float longer than usual or dive rapidly to the ground, or unexpectedly to veer off—all con-

tributing to unusual maneuvers and catches (surprise) and misses (disappointment). The net result of such play is a high level of reward and positive dissonance (elation). Control modules and routines established in the context of play are highly durable and resistant to extinction. When properly carried out, play-rewarded behavior gradually becomes play itself, making the opportunity to perform the behavior its own reward. Play has the ability to educe and shape drive-related behaviors into unique and usable forms with a rapidity that cannot be accomplished by other means of reward. The playful eduction and entrainment of drive-related modal activities is the basis of many practical dog-training activities. Working dogs work to play and play while working.

Diverters and Disrupters

In accordance with the control-incentive theory of reinforcement, attractive and aversive events are only reinforcing to the extent that the dog is actively engaged in efforts to control them (see *Diverters and Disrupters* in Volume 1, Chapter 7). For example, tossing a dog a piece of food while it is straining on the leash in order to play with another dog would not likely strengthen the pulling response, certainly not as much as might occur by letting go of the leash (see the previous discussion regarding the Premack principle). Similarly, throwing a treat to a dog while it is aggressively barking at a passerby will not likely reinforce the barking behavior, but if the person happened to run away in response to the dog's threats, then such territorial behavior might be strongly reinforced. In both cases, the presentation of noncontingent treats may interrupt instrumental behavior by exciting motivational interests irrelevant or incompatible with the rewards being sought by the dog at the moment. If the diverter performs an establishing-operation function, the dog will subsequently exhibit instrumental efforts aimed at controlling the diversionary stimulus. Under the influence of a control incentive, the diversionary stimulus may become a reward capable of performing a reinforcement function. However, even if a control contingency were inadvertently established between the barking behavior and the food item presented as a diverter, the barking response would be gradually stripped of its defensive significance via the classical conditioning effects of food reinforcement. Now, although a passerby might function as a discriminative stimulus for barking to get food rewards, the barking behavior would be of a very different motivational nature than aggressive barking and more readily controlled via a contingency of reinforcement now under the trainer's control. Disrupters are typically startle-producing stimuli that serve to interrupt behavior momentarily but without necessarily mediating a punitive effect. For example, in the case of a barking dog that ignores food at such times, a burst of compressed air might momentarily interrupt or briefly stop defensive barking. The brief hissing sound might immediately stop the behavior, but the effect may not last for long or significantly alter the future occurrence of the barking response. However, if the hissing startle is repeatedly presented under similar circumstances when the dog barks and is immediately preceded by some avoidance signal (e.g., "Quiet"), the dog may gradually learn to control the occurrence of the aversive event by not barking while in the predictive context or by stopping when the vocal avoidance signal is delivered. A preferable approach, though, is to follow the disrupter event with reward-based training efforts aimed at shaping responses incompatible with defensive barking (e.g., sitting or standing quietly for food and petting in the presence of the target). The combination of interruption and reward-based training can strongly enhance control efforts.

Directive Prompts and Blocking

Directive prompts and reprimands are the most common procedures used to enhance attention and impulse control. Although directive procedures can be highly effective and efficient, they can also produce significant fallout when used improperly or excessively (see *Coercive Compulsion and Conflict*

in Volume 1, Chapter 8). Attention and directive prompts serve the purpose of limiting behavior that disrupts or interferes with reward-based training objectives, especially behavior occurring under the influence of competing distractions, that is, extraneous establishing operations and sources of reward not under a trainer's control. In addition to capturing the dog's attention and enhancing impulse control, an obvious advantage of vocal and directive prompts in training is the ease and immediacy with which a highly motivational state (establishing operation) can be produced and exploited. Directive prompts perform two functions at once: they block or inhibit undesirable behavior (compel abstention) while at the same time causing the dog to produce more acceptable alternative behavior (inducing action). Such procedures and techniques are particularly useful and beneficial for the control of harmful or potentially dangerous activities. The paradigm's simplicity and power to establish immediate motivational change and readiness to work has made the correct-and-praise method of training very popular over the years—a method that remains a standard and integral aspect of many fields of practical dog training, especially those activities requiring a high degree of control and performance reliability. The firm and unshakeable reality of dog training is that some amount of compulsion is unavoidable.

Distractions: Extraneous Sources of Reward

Since no natural environment is completely free of distractions, a significant portion of training time is dedicated to gaining control over behavior operating under the influence of extraneous rewards. In a certain sense, distractions represent a valuable source of potential rewards not yet under a trainer's control. Staging training activities so that distractions can be made available to the dog on a contingent basis represents a powerful means to reduce the disruptive effects of distractions as well as serving to advance training objectives. The combination of response-blocking and directive techniques within the context of reward-based training activities facilitates the process of harnessing extraneous rewards to constructive goals. For example, preventing a dog from playing or chasing after another dog can be followed by an opportunity to engage safely in the activity, so long as it first waits and defers to the trainer's control prerogatives. Exploratory distractions of various kinds can be provided on a contingent basis provided that the dog periodically turns its attention to the trainer on signal, comes when called, and so forth. Since naturally occurring sources of reward are difficult to control and potentially dangerous to give on a contingent basis, motivationally equivalent activities may need to be identified and given to the dog instead. An alternative for dogs that enjoy chasing animals is the provision of tug-and-retrieve games, especially ball and flying-disk play. Dogs that engage in excessive exploratory behavior can be encouraged to play various hide-and-seek games in which toys are hidden for them to find.

Some extraneous sources of reward cannot be reliably controlled through the aforementioned procedures but may simply need to be inhibited and replaced with an alternative behavior. Directive training efforts are carried out to proof the dog's compliance under a wide variety of circumstances and distractions. Such training codes distractive stimuli into inhibitory signals, causing the dog to wait or stop when exposed to them rather than stimulating increased arousal and loss of control. Inhibitory training is recommended in the case of persistent behaviors posing significant potential harm to the dog or others. For example, dogs that chase after cars, bicyclists, joggers, and so forth may simply need to learn to avoid such activities by the application of appropriate commands, reprimands, and corrections. As the result of well-timed and appropriately impressive corrections, such dogs gradually become more responsive to commands and reprimands in the face of distracting influences. Gradually, by means of associative learning, distractions become conditioned into avoidance or inhibitory signals rather stimuli triggering arousal and chase behavior. For example, many dogs exhibiting the unacceptable habit of chasing cats quickly learn, after the delivery of a few directive leash prompts or electrical corrections, that

lunging after a fleeing cat only results in discomfort and nonreward—not the attainment of the anticipated joys of the chase. As a result, the dog learns to approach cats with improved self-control, first hesitating and then gradually learning to avoid chasing them altogether, and finally learning to ignore them or to expect food rewards in their presence as the result of concurrent reward-based attention and sit-stay training efforts. The overall effect is to improve the dog's attention to the trainer's instruction whenever a cat happens to be nearby.

Least Intrusive and Minimally Aversive

Correction procedures should not be used lightly or haphazardly. The rule of thumb is to select the least aversive and intrusive procedure that is reasonably expected to succeed. According to the least intrusive and minimally aversive (LIMA) model, aversives are ranked in terms of their relative severity and intrusiveness, requiring that the trainer apply a less aversive technique before advancing to a more aversive one (see *Compliance* in Volume 2, Chapter 2). Adhering to this model and selection process ensures that the least necessary and sufficient aversive procedure is used to produce the intended behavioral objective. In addition to minimizing the potential for producing pain and discomfort, correction procedures should be governed by a principle of minimal intrusiveness. Training procedures should intrude minimally on the human-dog bond and avoid adversely affecting the dog's quality of life. Overly constrictive restraint and confinement techniques should be avoided in favor of techniques that most rapidly and humanely achieve training objectives without causing undue distress or discomfort to the dog.

PART 2: TOOLS AND TECHNIQUES

Training Tools

The equipment used in dog and puppy training is fitted with a concern for the dog's age, size, temperament, training history, and specific needs. A wide range of products of varying quality and price are available. Training equipment should be of the best quality, remembering that cheap equipment is most likely to fail when it is needed most. All training tools have advantages and disadvantages that need to be considered carefully, and each requires a degree of expertise for proper use. Although some rather vitriolic and unproductive hyperbole bubbles up now and then against the use of various training collars, most experienced and competent trainers agree that such tools have a functional and humane place in dog training. Any standard training tool can be used abusively and cause injury, but there is nothing inherently cruel about such tools (see Delta Society, 2001). Although neck injury can result from the improper use of a slip or halter collar, I have personally never witnessed or know of a single verified case in which a dog sustained serious cervical injury as the result of a properly applied leash correction, even involving corrections that have been applied very forcefully. Some dogs (e.g., the toy poodle and Yorkshire terrier) appear to be predisposed to tracheal problems and should be trained on harnesses. If in doubt about the suitability of a specific collar for a particular dog, consult a veterinarian for advice.

Flat-strap and Martingale Collars

For many dogs, commercially available flat-strap and buckle or so-called martingale collars are sufficient for most training purposes. The flat collar is tightened just snugly enough to prevent it from slipping over the dog's head. When properly fitted, the martingale collar has the advantage of a slack fit with little risk of the dog backing out of it. Puppies under 5 months of age are typically trained with a strap collar alone or a fixed-action halter. In the case of strong puppies and dogs, a buckle-type fastener is preferred over a plastic snap-on one.

Limited-slip Collars

A highly effective limited-slip collar can be made from a single length of nylon webbing (Figure 1.3). The primary advantage of the limited-slip collar is adjustability, both in terms of the range of slip action and the pressure

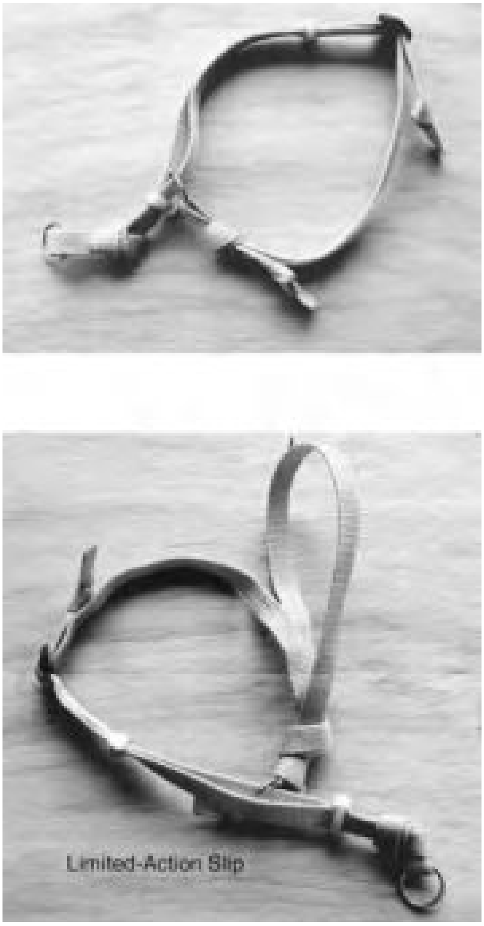

FIG. 1.3. Limited-slip collar (top) and limited-slip/halter combination collar (bottom) provide excellent control and adjustability.

applied to a dog's neck. The limited-slip collar features two slides that are used to make these adjustments. As in the case of full-action slip collars, the limited-action collar is placed around a dog's neck so that it forms a "p for perfect" (frontal view). Another way of making sure that the slip collar is on properly is to observe how the collar closes. When pulling the live ring (the one hooked to the leash), the collar should close dragging the dead ring clockwise around the dog's neck.

Conventional Slip Collars

Many trainers prefer using a nylon-slip or chain-slip collar—a collar that remains especially popular among working-dog trainers. The chain-slip or check collar consists of a chain with two rings, the live ring and the dead ring. The leash is attached to the live ring, causing the dead ring to travel clockwise around the dog's neck as it applies momentary pressure. The term *choke collar* is a misnomer that may have contributed to a significant misunderstanding about the use of such collars, as evident among inexperienced dog owners who purchase them to control pulling dogs. Many people use these collars under the false assumption that they work to stop pulling behavior by choking the dog. Consequently, under the belief that the choking effect will eventually discourage pulling, they allow the dog to pull continuously during walks. This belief is not only wrong with regard to the reduction of pulling behavior, but such control by choking may also produce significant physiological distress and harm (see *Walking on a Slack Leash*). The size of the chain-slip collar is estimated by measuring the widest part of the dog's head. A chain-slip collar can be made safer by placing a key ring through the chain to block the collar from closing too tightly around the dog's neck, thus limiting the amount of compression to the neck that the collar can deliver (Figure 1.4). In addition, a split ring can be attached to the chain to prevent it from sliding through the dead ring, thereby helping to keep the collar in place on the dog's neck. The training slip collar requires significant skill to be used properly and safely.

Prong Collars

The prong collar features a high degree of adjustability by way of removable prong links that are positioned to press into a dog's neck as the leash is pulled back (see Figure 1.4). A chain with two opposing rings (the center ring and swivel ring) closes the collar with an action similar to that of the martingale collar. The prong collar can be converted into a martingale collar by turning it around so that the prongs face away from the dog's skin. The leash is attached to the swivel ring. The center ring on the reciprocating chain slides from side to side. The side-to-side action of the central ring serves to direct prong pressure

FIG. 1.4. Limited-slip chain (chain-slip) collar (top) and micro and small prong collars (bottom). The chain-slip collar can be modified to yield enhanced adjustability and safe control over the slip action.

differentially to different parts of the dog's neck. When pulled straight back, the chain causes the prong collar to close evenly around the dog's neck. When the leash is pulled toward the right, the center ring shifts position and catches on prong links that direct most of the leash pressure to the left side of the dog's neck, causing it to move to the right in a highly controlled way. These actions and effects are useful for shaping and polishing precision heeling. The proper use of the prong collar as a shaping and polishing tool requires significant instruction, but with respect to basic control uses novice trainers can rapidly master the prong collar. It is frequently used to train high-spirited working dogs.

Halter Collars

A variety of halter collars are currently on the market. Most of these can be traced to an original concept and design fashioned by Alice DeGroot and patented in 1984 (Figure 1.5). DeGroot's K-9 Kumalong design offers significant head and muzzle control while at the same time allowing the dog to open its mouth fully. The basic logical and mechanical principle of DeGroot's collar is that "where the dog's head is led, the body is sure to follow." (DeGroot, 1985:30). In addition to improved head control, the muzzle action of the collar provides a source of negative reinforcement and jaw control. Whenever a dog

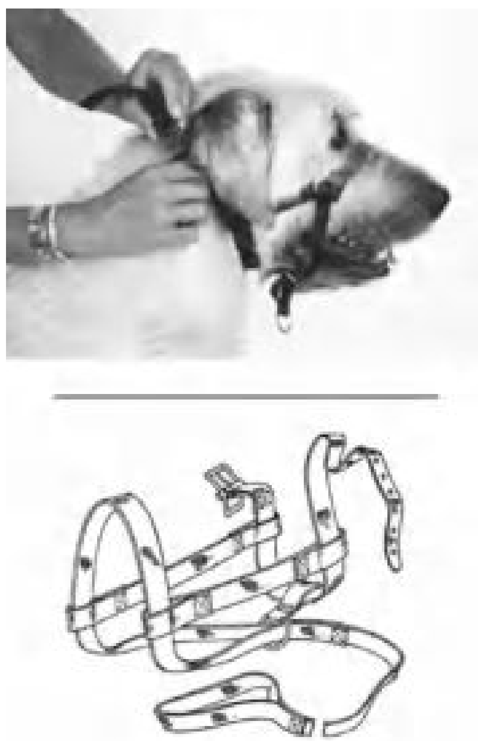

FIG. 1.5. K-9 Kumalong.

pulls back against the leash, the clamping action of the muzzle loop closes the dog's mouth, an effect that is immediately reversed when the dog stops pulling. DeGroot suggests that part of the halter's effectiveness may stem from ethological origins, in particular, from the way in which the mother disciplines or reorients her puppy by manipulating its muzzle. She argues that the Kumalong muzzle loop provides "surrogate maternal control" (31), an effect that adult and dominant dogs may resent, causing them to resist halter control fiercely when they are first exposed to it. Although some dogs may become momentarily reactive to halter restraint, others appear to become progressively relaxed and calmed as the result of it, an effect that DeGroot claims is especially prominent in hyperactive, nervous, or timid dogs. She speculates that the tranquilizing effect of halter control may be due to endorphin release, perhaps involving a mechanism similar to that attributed to the tranquilizing effect of acupuncture treatment.

With the advent of muzzling-type halters, the slip action of the traditional training collar shifted from around the dog's neck to a more vulnerable point around its muzzle. The muzzle-controlling loop effortlessly twists and turns a dog's head when it pulls, while forcefully pinning the dog's mouth shut if it attempts to struggle or back out of the collar. Of course, the capability of such collars to control the head and exert a forceful muzzling action is a desirable innovation in the case of aggressive dogs, providing trainers with increased control and safety over such situations than afforded by conventional collars. A subsequent halter design marketed under the trade names Promise and Gentle Leader was patented in 1986 by R. K. Alexander with two co-inventors, as a combination collar and muzzle training aid. Over the years, Anderson has been an enthusiastic proponent of halter training in the context of veterinary behavior management and therapy. The collar-muzzle combination provides secure control over a dog's head movements, produces a robust muzzle-clamping action, and features a fixed-muzzle capability. Releasing and moving up a plastic adjusting slide located on the muzzle loop and resetting it at a point that prevents the dog from opening its mouth produces a partial muzzle effect. Although a muzzle set in this way prevents wide-mouthed bites, dogs can still manage to pinch with their incisors. Clamping the muzzle loop down farther to completely prevent pinching bites is not recommended, since it results in significant discomfort and distress to dogs. In such cases, or in cases involving a serious risk of attack, a mesh-sleeve or basket-type muzzle should be used instead of a muzzle-type halter.

Most dogs exposed to halter collars exhibit varying amounts of struggle and distress before finally accepting the restraint (Haug et al., 2002). After several brief sessions of introductory training with treats and patient encouragement, the vast majority of dogs calm down and learn to accept or at least tolerate the collar. The odor of orange oil (2 or 3 drops) rubbed on the hands or presented from a scented squeaker bulb can exert a potent calming effect over persistent reactivity to halter restraint when presented to the dog to sniff. The subsequent presentation of the odor of orange appears to work as both a calmative and a positive reinforcer to maintain more relaxed behavior. However, some dogs simply will not accept such restraint and react with persistent and vigorous protest and present an appearance of significant distress. Aggressive dogs (especially experienced biters) that resent the halter represent a significant risk to trainers or owners when they attempt to put the halter over the dog's muzzle.

Although one would expect to find significant differences in the biological stress exhibited by dogs wearing flat collars versus halters, a study performed at the University of Minnesota found no significant stress-related physiological differences between the Gentle Leader and a flat-strap collar (Ogburn et al., 1998). Head collars should be used with great care, since they work by twisting a dog's head and neck. Excessively hard corrections or surprise lunges by the dog could result in cervical strain or injury, especially in dogs predisposed to such injury, but to my knowledge no confirmed injuries of this kind have been reported. Halters can produce friction sores on the top of the muzzle, but careful fitting and proper use of such collars prevent most of these problems. In the case of

adult aggressive dogs, halters should be used in combination with an oversized slip collar that is sufficiently long not to interfere with the clamping action of the halter. The backup collar prevents dogs from breaking free during unexpected episodes of intense struggle or when the halter might accidentally come off or fail in some unforeseen way. Alternatively, a backup collar and halter can be fastened to the same leash by hooking a small carabiner through the handle of the leash and attaching it to the collar. The leash forms a closed loop between the collar and halter and is held with both hands, the left hand controlling the collar and the right hand controlling the halter.

Another closed-loop arrangement uses a hip-hitch (see *Hip-hitch*) in combination with a flat strap or limited-slip collar and halter (Figure 1.6). A leash fitted with a small carabiner hooked to the handle of the leash is used. Alternatively, a service leash with bolt snaps at both ends can be used. The carabiner is attached to a strap or limited-slip collar, and the other end of the leash is hooked to the halter, functioning as a control lead. The arrangement provides a closed loop in which forceful pulling is blocked with the hip-hitch, while the halter is used to guide the dog rather than hold it back. This arrangement appears to be safer and more acceptable to many dogs, especially those reactive to halter control. The combination also appears to facilitate active training rather than simply controlling the dog via passive halter restraint. The undesirable clamping action produced by the conventional halter can be eliminated by the arrangement, unless the trainer wishes to produce such additional restraint with the control lead. The use of a hip-hitch and collar in combination with the halter makes the introduction of halter control less evocative and stressful. Instead of functioning as a tool to passively control pulling by forcefully twisting a dog's head, the combined hip-hitch, collar, and halter arrangement allows the halter to be used in a much more gentle way. The arrangement makes fading of halter control easier as more appropriate walking behavior is shaped under the control of the strap or limited-slip collar. Finally, a major advantage of the hip-hitch is that it frees the trainer's hands to present various hand signals, bridges, and rewards, while minimizing the risk that the trainer might accidentally lose control of the leash.

Fixed-action Halter Collars

Although the muzzle-clamping action of most halter collars is highly effective and useful, for most basic training purposes a fixed-action halter is adequate when the added control of a halter is needed. The fixed-action halter has two significant advan-

FIG. 1.6. Closed-loop arrangement with flat collar and fixed-action halter.

tages: snug fit and comfort. The nonclamping muzzle loop ensures that pressure will be appropriately delivered to the back of a dog's head when it pulls back, rather than unnecessarily clamping down on its nose. When the dog pulls ahead, the neck and muzzle loops effectively serve to turn the dog's head, but without putting any unnecessary pressure or rubbing on the dog's muzzle. Fixed-action halter collars provide an excellent transitional means to control excessive pulling in puppies and adult dogs alike. The muzzle loop is formed by tying a figure-of-eight loop or simple overhand loop into an 8-foot length of nylon webbing, leaving a short end to form a neck loop and the remaining long end to make a leash and handle (Figure 1.7). The short end forms the neck loop by slipping it through the muzzle-loop knot and then tying it off to the leash

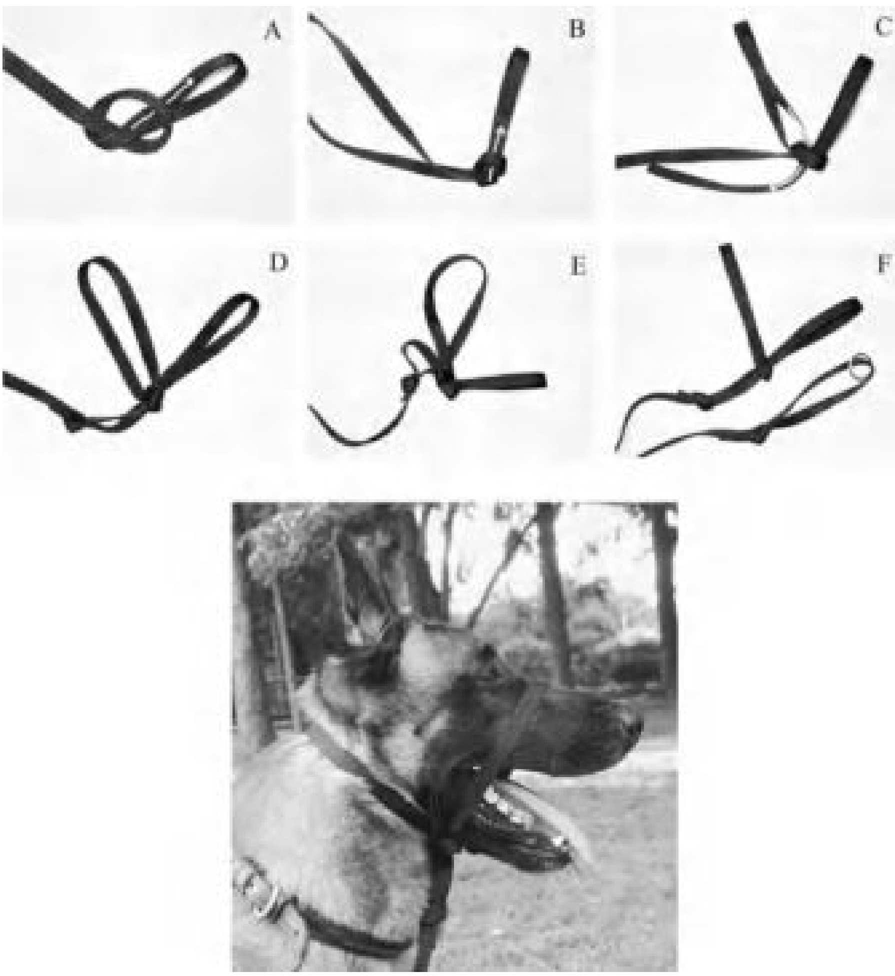

FIG. 1.7. Fixed-action halter. (A) The muzzle loop uses either a figure-of-eight or an overhand loop knot. (B) A finished muzzle-loop knot. (C) The neck loop is formed by slipping the short end through the muzzle-loop knot. (D) A finished halter with the adjusting knot binding the neck loop to the leash. (E) A fixed-action halter is opened by sliding the neck loop through the muzzle-loop knot. (F) A fixed-action halter with handle measured and ready for use as a muzzle-clamping halter.

end approximately 4 to 8 inches below the knot, depending on the size of the dog's neck and head. When fully pulled out, the neck loop should fit snugly, thus preventing the dog from backing out of it, but it should not press uncomfortably around the dog's neck. Once tied off to the leash, the neck loop can be opened by pulling it back through the muzzle-loop knot, thereby expanding it so that the neck loop can get over the dog's head. Before it is closed again, the collar loop is situated just behind the dog's head, and the muzzle loop is placed over its nose. To close the neck loop and secure the muzzle loop in place, the left hand grips the muzzle-loop knot while the right hand pulls the neck-loop knot back, thereby causing the neck loop to tighten and the muzzle loop to move back into place on the dog's nose. The fixed-action halter and leash are continuous with a handle tied into the end of the leash.

In addition to fixed-action halters, a limited-slip/halter combination collar is often used in training (see Figure 1.3). The halter/limited-slip collar combines the advantages of both the halter and slip-action collar, while minimizing some of the disadvantages of conventional slip and muzzling-type halter collars. By distributing force between the limited-slip collar and the muzzle loop, the halter/limited-slip collar provides enhanced head control without excessive clamping or twisting actions. Excessive neck twisting is prevented by the automatic transfer of force from the muzzle loop to the limited-action slip collar. The relative amount of force directed to the neck or muzzle is adjusted by moving the slip-limiting slide on the collar. The flat collar, the limited-slip collar, the fixed-action halter collar, and the halter/limited-slip collar combination are the primary collars used in cynopraxic training.

Fixed-action and Slip-action Harnesses

In cases involving dogs with a propensity for tracheal problems or a veterinary diagnosis counterindicating the use of a collar around the dog's neck, a harness can be a useful alternative. Various designs are available, and proper fitting is critical to prevent the dog from getting out of the harness. Full and half-slip harnesses can be easily made with nylon webbing.

Leash and Long Line

The best training leashes are made of harness leather with a brass bolt-swivel snap braided into the end of the leash. However, a well-stitched nylon or cotton-web leash is also acceptable, especially for puppy training. For most purposes, the leash should be about 6 feet long with a weight and width determined by the training needs, the collar, and the size of the dog. A light leash is preferred for use with a halter. The long line is a 30- to 50-foot length of cotton webbing fitted with a bolt-swivel snap or a one-quarter to five-sixteenth-inch braided white nylon rope that is tied off with a limited-slip collar and knotted handle (Figure 1.8). The white rope long line is preferred for visibility and stretch, whereas the primary advantage of cotton webbing is the absence of stretch when it is pulled taut. The long line requires careful and attentive handling if one is to avoid severe friction burns and other potential injuries resulting from the abrupt force generated by it. Long-line training should be performed in well-controlled surroundings without playing children or dogs nearby, and all observers in the situation should be

FIG. 1.8. Long-line with limited-slip collar tied with a series of overhand knots.

warned of the potential risks and dangers associated with long-line training. Observers are instructed to stay out of way and how to remain on the outside of the line. The trainer should always wear pants and appropriate shoes when working a dog on a long line. Grabbing a long line with bare hands is risky and should be generally avoided. Instead of grabbing it, the trainer should tamp or stamp on the long line to control the dog. If the long line must be handled with the hands, light leather gloves can be used to prevent friction burns. Gloves are generally a mixed blessing, however, since the safety afforded by them is achieved at the cost of losing a sensitive feel for the line. Also, the added security of gloves may cause inexperienced trainers to use the long line without proper respect, perhaps increasing the risk of other more serious injuries (e.g., fingers getting caught and broken). When holding the long line, it should be kept organized in neat folds and carefully managed to prevent it from becoming wrapped around the dog's feet, legs, or body. The long line is carefully folded at the end of training sessions. Before using the long line to control highly motivated behavior, the trainer should first become skillful with it in less demanding situations (e.g., playing ball) and acquire an appreciation for its safe use. Temporary overhand loops can be tied at various points along the line to hook into with the leash, thereby providing the trainer with a secure source of backup control if it is not possible to step on the line.

Hip-hitch

A useful tool for controlling pulling excesses is the hip-hitch and control lead. The simplest hip-hitch method consists of tying a 12- to 20-inch loop in the leash and hooking it to a carabiner held in place at the left hip by a belt. The remaining leash and handle, referred to as the control lead, is used to guide and fine tune control. The hip-hitch requires skill, coordination, and careful attention to various precautions, especially when working with large dogs (see *Controlled-leash Walking and Hip-hitch*).

Miscellaneous Items

Other items of equipment include a carpenter's apron or small treat pouch, a tennis ball with a handle, and treats (Figure 1.9). The most effective commercial dog treats are usually moist and possess a strong odor. Microwaved turkey or chicken hot dogs can make an attractive food reward. The treats are prepared by finely cutting a hot dog into pennywide slices. The pieces are spread out evenly on a paper towel or plate and cooked in a microwave for 2 to 3 minutes or until leathery to touch but not dry. Hot-dog treats are used in small pieces torn from the microwaved slices. Each slice can produce between 3 to 10 rewards, depending on the size of the dog. Chicken or turkey lunchmeat can be partially dried in the microwave and used in a similar way. Small biscuits, cheerios, cornflakes, popcorn, and so forth can be mixed in with hot-dog treats or be coated with the powder produced by microwaving hot dogs until they are dry and then crushing them. Another possibility is to mix some of the dog's kibble with a small amount of finely grated Romano or Parmesan cheese. Crated hard cheese can be sprinkled lightly on cheerios or similar treats and microwaved to give them additional value as food rewards. A tool of considerable usefulness in dog training is the shaker can, which

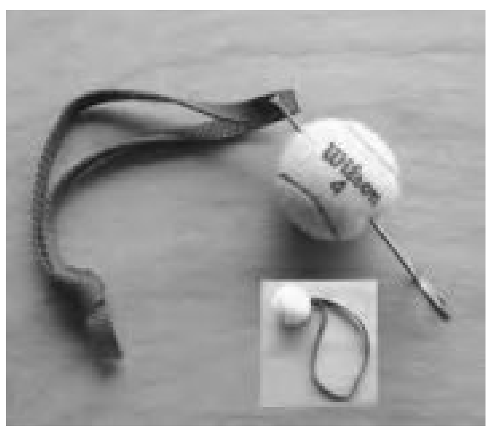

FIG. 1.9. Tennis balls used in training should be equipped with a handle.

is made from an aluminum soda can that has been rinsed and allowed to dry. Usually, two cans are made: one containing seven pennies and the other 30. Turning the finger tab around so that it covers the opening helps to block the pennies from falling out but without muffling the sound, as occurs when tape is used to close the can. Another disrupter-type device that can be very useful is the modified carbon-dioxide pump, which delivers a highly effective hissing sound for getting the dog's attention without producing pain or sensory discomfort. The modified carbon-dioxide pump can be used to deliver conditioned and unconditioned odors, giving it additional usefulness in a variety of applications.

Bridges, Markers, and Flags

During the 1960s, Leon Whitney (1961 and 1963), a veterinarian, breeder, and pioneering dog trainer, first introduced clicker training to the dog-training community. The method of shaping instrumental behavior with a clicker, first described by Skinner (1951) and more recently popularized by Pryor (1985), uses the sound of a clicker that has been repeatedly paired with food to bridge successive approximations of some target behavior with a contingent, but not immediately available, food reward. Unfortunately, clicker training was largely overshadowed by other prevailing techniques that remained relatively dominant in the field until recently. Over the past decade, however, many applied dog behaviorists and trainers have rediscovered the value of the clicker and the technique of shaping. Of course, any distinctive sound (e.g., a click, squeak, or trill) can be used as a bridging signal. Although valuable and effective for purposes of conditioned reinforcement, clickers and other mechanical markers and bridging stimuli have two inherent practical drawbacks: (1) they can be unwieldy for the average dog owner to use, and (2) they are not always immediately at hand when needed. With instruction and practice, most owners can learn how to use a clicker effectively, but such devices should be not be used with the intent to replace conditioned vocal bridges (e.g., "Good"). The squeaker and clicker are especially useful in situations requiring precisely timed conditioned reinforcement (e.g., attention training and shaping procedures) or repeated bridging (e.g., controlled-walking or heeling patterns). In addition, the clicker and squeaker can play a valuable role in the treatment of behavior problems. The clicker provides a discrete and salient stimulus that may help to obviate adverse emotional cues projected unawares in vocal signals. In the case of fearful dogs that are startled by the sharp click sound, a recording of the clicker can be made and delivered with an inexpensive digital recorder (Figure 1.10). The reduced volume of the recorded click sound is less likely to produce a startle response. A major advantage of the clicker and other mechanical bridge signals is that their effect can be conditioned and easily transferred from one person to another without losing potency.

The relative neutrality and clarity of the hiss, beep, click, or squeak can be highly effective for diverting the dog's attention or bridging orienting and attending behavior with reinforcement. Squeakers possess an added potential use obtained by putting an odor inside of them and dispensing it with or without the squeak sound. When dispensed at close quarters (e.g., as the dog sniffs the hand), the odor is released a split second before the squeak sound is generated. The

FIG. 1.10. Different clickers that produce varying levels of sound. The box clicker is equipped with a squeaker element that can be used in combination with the clicker during attention training.

odor can be deliberately arranged to precede the squeak by gently "pulsing" the squeaker bulb, so that the odor is dispensed but without the squeaker sound. Pulsing gives the odor time to reach the dog before the squeaker sound is produced, together with the delivery of a stronger odor stimulus as the squeaker bulb is more firmly squeezed. As the result of repeated pairings of the odor or the odor-squeak combination with food, taction, and other sources of reward, the odor and squeak gradually acquire unique conditioned properties that can be used in a variety of creative ways to modulate reactive thresholds and control attention. In addition to producing a distinctive sound, the squeak, unlike the click, can be varied in various ways, depending on the pattern of squeaking sounds produced or the force used to deliver them, thereby preventing habituation and enhancing its ability to grab the dog's attention. Gently pressing a small amount of air out produces a weak squeak sound, whereas forcefully pressing a full bulb of air through the squeaker valve produces a much louder and more impressive sound. In many cases, the squeaker has already undergone significant conditioning as an auditory stimulus in the context of playing with squeaker toys. Finally, the squeak sound is rapidly conditioned as a bridge or orienting signal, suggesting the possibility that it may be biologically prepared for forming associations with appetitive (seeking) or social activity. Small animals in distress often squeak in a similar way, perhaps helping to explain the apparent preferential and rapid association that can be made between the sound of the squeaker, conditioned odor, and food. Similarly, the squeaker and smooch sound (a powerful orienting stimulus) may be innately attractive and reinforcing. Ryon (1977), for example, found that a captive wolf mother called her 3-week-old pups out of the den interior to its entrance by squeaking.

Normally, dogs are first taught vocal bridging signals (e.g., "Good," "Yes," "That's it," and "Wow"), reward-delay or nonreward markers (e.g., "No," "Phooey," "Wrong," "Eh, eh," "Ack," and "Nah"), and flags (various hand and bodily movements used to momentarily direct a dog's behavior), with the goal of improving the owner's vocal control and other communication efforts. Unlike mechanical bridges or markers, voice and hand signals are charged with human emotional expressiveness—content and meaning that provide significant and valuable secondary bonding and socialization effects. Expressive affectionate talk and gestures help the trainer to transact and connect with the dog via an emotionally activated conduit of empathetic appreciation. The mélange of gross and subtle emotional expressions associated with human approval and disappointment, together with variations of touch (ranging from the gentle stroke to the abrupt shove), all contribute to a dog's fullest socialization and development as a companion. In sum, socially significant and emotionally charged consequences facilitate a profound level of mutual awareness, exchange, and bonding between people and dogs. Optimal training incorporates the broadest possible spectrum of motivational incentives and behavioral potentials of a dog.

Mechanical reinforcers and training techniques tend to promote a push-button attitude toward a dog's behavior and its modification. Although mechanistic precision and efficiency are valuable for attaining certain practical training objectives, excessively technical means may inadvertently interfere with the bond-enhancing goals of cynopraxic training. Both the clicker and other precise mechanical means (e.g., the remote electronic collar) are powerful and effective tools with which to control dog behavior. The effectiveness of these devices has caused them to become increasingly popular among trainers and the dog-owning public, with one company marketing a product that incorporates both a click feature for delivering conditioned reinforcement and an electrical stimulus for delivering negative reinforcement and punishment. With regard to the goals of cynopraxic training, the mixture of expressive voice, gesture, touch, and play are preferred to mechanical bridging stimuli or remote stimulation that target a narrow range of motivational systems. However, the clicker's simplicity and clarity provide a significant advantage for some training activities, such as walking a dog on a slack leash, shaping attention and orienting behavior, and recall—all can benefit from the

immediacy and consistency of mechanical bridging stimuli.

The Training Session

A training session usually consists of a series of repeated trials that are performed with some goal or training objective in mind. Training trials consist of antecedent and consequent events or conditions that are arranged by the trainer to enhance predictive control over a target segment (module) or sequence (routine) of dog behavior. Trials are separated by intertrial periods, usually consisting of less controlled and more natural modal activity and interaction between the trainer and the dog. Many trials are initiated by calling for the dog's attention, whereas releasing the dog with an "OK" and clap often marks the beginning of intertrial periods. Within the context of a training session, trials and intertrial periods are organized into lessons and goal-oriented projects. The practice of modules and routines in conformity with the goals of the project is referred to as an exercise. Projects give structure and purpose to the training session and help to integrate and pattern modules and routines around active and passive modal strategies. Within the context of the training session, special modal outcomes (play and time-out) are arranged to mediate modal integration via sustained surprise and elation (active modal strategy) and disappointment and de-arousal (passive modal strategy). Training sessions organize trials, lessons and exercises (modules and routines), and projects in accordance with the objectives of the training program (e.g., solving a behavior problem). Training activities and procedures are typically introduced and broken down into a series of discrete steps, exercises, and projects (training plan) that are practiced by the owner between sessions. Finally, training activities are performed in accordance with cynopraxic goals and vision.

The steps making up the training plan are organized so that preliminary work prepares the way for the dog to learn what follows next more easily and efficiently, moving from simple modules to progressively more complex routines and skills. Ideally, the training process should proceed with minimal error and tension, becoming a source of fun and mutual reward for both the trainer and the dog. In addition to vocal affection, petting, and food rewards, play activities of various kinds are used to activate control incentives and to reward trained behavior. A brief period of ball play is often used to initiate practice sessions. The ball is also presented periodically during the session as a surprise to enhance interest and to associatively link the trained modules and routines with play. Tug and ball play should also conclude the session to further associate trained behaviors with play, thereby gradually integrating trained behavior with modal play. The session period varies according to the dog, its age, the lesson, and other considerations (e.g., health and temperament). Puppies can benefit from very brief sessions consisting of as little 3 to 8 minutes, but can happily perform and enjoy much longer sessions, provided that the process is reward dense, affectionate, and playful. The average training session for an adult dog is around 20 minutes, including 5 to 10 minutes dedicated to play and agility activities, such as jumping over poles, hoops, and hurdles, and running through weave poles. Longer or briefer sessions are also used depending on training objectives. Training sessions can be scheduled two or three times a day. In addition to training activities performed in the context of structured sessions, a strong emphasis is placed on integrating training activities into everyday activities via ICT.

Play Training

Basic training constrains and focuses natural learning capacities and incentives to obtain behavioral objectives that are often unnatural and occasionally unpleasant or annoying for a dog to perform. Some learning occurs rapidly, and may even be fun for the dog, because it takes advantage of innately prepared associations and drives. Behaviors occurring naturally in the process of play are most easily trained and brought under the control of ludic incentives. Teaching a dog to fetch a ball, for example, is highly prepared and easily learned by most dogs. For many dogs, the opportunity to play ball is hedonically far

more valuable than getting a delicious food reward. Because such dogs love playing ball, the activity can be exchanged for the performance of other behaviors that a dog may not find as enjoyable; that is, ball play can be used as a potent incentive and source of reward. As a result, trained modules and routines can be gradually patterned into modal play activities—a procedure that is widely used in the training of working dogs, making necessary skills more enjoyable for them to learn and perform as the work becomes associatively integrated with play and its performance becomes its own incentive and source of enjoyment (see *Training and Play*).

Every dog should learn to play ball. Older dogs that have not been exposed to play at an early age may not show much interest in the activity, but many can be motivated with patient encouragement and playful stimulation. To increase interest, the trainer might tease the lackadaisical fetcher by repeatedly bouncing the ball against a wall, causing it to fly enticingly close to the reluctant player. Another useful method is to play keep away by kicking or flicking the ball just out of the dog's reach. If the dog happens to pick the toy up, it can be engaged in a gentle tug contest for possession. Interest in the ball can also be enhanced by playing "monkey in middle," keeping the ball just out of the dog's reach. At a point when the game reaches a sufficient pitch of excitement, the dog can be allowed to get the ball and keep it for a moment before being called to exchange it for a treat. Playing tug with the dog helps to improve ball drive and its willingness to chase and bring the ball back. Finally, ball drive can be enhanced by keeping the ball away from the dog at all times other than when it is used for play or training. The goal of ball play is to make the dog a fanatic about the ball! Often a few drops of a conditioned odor (e.g., lemon or orange) are put inside the ball to establish an association between the scent and the play activity. Such conditioned odors can be effectively used in the management of a variety of behavior problems.

Getting a dog to chase a ball is often more easy than getting it to bring it back. Many dogs welcome the opportunity to play keep away, especially if the owner is game and offers a chase. Keeping the dog on a long line and giving it a treat in exchange for returning and releasing the ball helps to encourage good retrieving habits. Each time the dog returns with the ball, a food reward is offered to it, causing the dog to release the ball in order to obtain the treat. After a moment, the ball is tossed again, and the dog is encouraged to return with it by making smooch sounds, clapping, crouching down, and so forth. Training the dog to come to a closed hand for a variable food reward is a useful preliminary for dogs that habitually refuse to return with the ball. Eventually, the release of the ball is brought under the control of a release signal like "Out," spoken just before the dog releases the ball. Another way of improving the dog's willingness to return with the ball is to use a second one as a trade. The dog is required first to drop the one it has before the second one is thrown. The long line provides additional control by preventing the dog from running off with the object or refusing to come back with it.

With a foundation of ball play and retrieve in place, an improved willingness to come when called can be developed. In fact, there is no better time to introduce recall training than during ball play. After sending the dog to retrieve the ball, but just before it turns to bring the ball back, the trainer says the dog's name and waits until it turns fully around before saying "Come" in a crisp and playful tone of voice. The command is followed by encouraging praise and clapping, crouching down, or running backward in the case of hesitant dogs to encourage them to come more enthusiastically. The dog soon learns that the command "Come" is linked with a treat and the opportunity for more play. Besides learning to come on command, the dog can also be taught to wait briefly before the ball is tossed again. This is accomplished by saying "Wait" prior to each throw while having the dog focus on the ball, thereby enhancing attention and impulse control under the strong motivation of play. The act of waiting is reinforced by the whole chain of events: the opportunity to chase, fetch, and drop the ball into the trainer's hand—all eventually leading to the acquisition of food and the opportunity to play again.

PART 3: TRAINING PROJECTS AND EXERCISES

Introductory Lessons

The introductory lessons are largely the same for both puppies and adult dogs. The goal of these early lessons is to establish a foundation of attention and impulse control within the context of reward-based training.

Bridge Conditioning

Conditioned reinforcers serve to bridge the occurrence of some target behavior with the delayed delivery of unconditioned reinforcers (see *Shaping: Training Through Successive Approximations* in Volume 1, Chapter 7). Consequently, conditioned reinforcers are often referred to as bridges or bridging stimuli. Bridge conditioning is usually carried out under relatively distraction-free conditions in the house or yard. A variety of soft and hard treats are prepared and placed in small hip pack or belt pouch, and the web handle of the ball is passed under the belt, making it easy to access. Both food pouch and ball should be kept on the trainer's right side. The dog should be slightly hungry and rested at the start of training. Social and food deprivation is rarely necessary to heighten the appetite of a healthy and emotionally balanced dog to work for food and social rewards. The first step in the process of conditioning the bridging stimulus or bridge is to allow the dog to sample the food reward from the right hand. Food treats should be consistently given with the right hand. A tiny piece of the food reward is given to the dog first from the fingers and then from a closed hand as it approaches. A small bit of food can produce a surprisingly strong food incentive, probably as the result of the dopamine reward signal produced by the activation of an olfactory incentive system (see *Olfactory Incentive System and Prediction Error* in Chapter 10). Modal seeking activity associated with food is rapidly invigorated and is highly responsive to the activation effects of surprise. The sampling or priming process is repeated until the dog enthusiastically searches and follows the trainer, seeking the food reward. As the dog reaches the trainer, the vocal bridge "Good" is spoken in a clipped and high-pitched tone just before the food reward is delivered to the dog from the right hand. The food reward should be concealed in a closed hand, requiring that the dog touch it and briefly wait, whereupon the bridge "Good" is delivered just before the hand is opened. Gradually, the dog should be encouraged to follow the right hand actively as it is moved in various directions before the reward is delivered. The trainer should move around the training area and encourage the dog to follow; as it turns, the trainer crouches down and flicks the right hand out to the side, attracting the dog's attention and saying "Good" as soon as the dog touches it. Alternatively, a clicker can be sounded just as the dog turns toward the trainer, and followed by the vocal bridge just before the closed hand is opened. The process of pairing the bridging stimulus with food rewards is repeated until the dog shows a clear anticipatory response to the sound of the bridge.

As a standard expectancy is established, variations can be introduced to enhance bridge conditioning. For example, varying the duration between trials, so that some occur sooner than others, produces a surprise in relation to the expected timing of reward. Also, varying the length of time taken to open the hand containing the food reward can also provide a similar element of surprise. Periodically, instead of having the dog come to the hand, the food reward is tossed to it immediately after the bridge (click) is delivered. As previously discussed (see *Prediction and Control Expectancies*), significant surprise and additional bridge-conditioning benefits can be generated by varying the size, type, and frequency of the reward given to the dog. In addition to conditioning the bridge in the context of reinforcing following behavior, the association can be strengthened by using it to enhance an orienting response whereby the dog is prompted to turn its attention toward the trainer in response to a smooch or squeaker sound followed by a click or "Good." After orienting or coming to the trainer, it can be prompted to make eye contact (attending response), whereupon the bridge and food reward are delivered. Affectionate petting should be frequently given along with food rewards. Affectionate petting

enhances the rewarding event as well as linking the affectionate activity with the bridge "Good."

Following and Coming

After each trial, the trainer steps back a step or two and encourages the dog to come along, guiding it to the left side with the right hand and causing it to turn about there, before stepping forward and encouraging the dog to follow along at the left side. Following behavior is bridged with the clicker, whereupon the closed hand containing a food reward is moved slowly over the dog's head, causing it to follow and sit. As the dog begins to sit, the bridge "Good" is delivered and followed by the food reward as the action is completed. Alternatively, after taking several steps forward, the trainer can call the dog's name and abruptly backpedal away from it, causing it to turn and follow along. Just as the dog turns, the trainer clicks and flicks the closed right hand off to the side. Just before the dog reaches the hand, the trainer says "Come" and then "Good" just before the hand is opened to reveal the reward. At the conclusion of this simple chain, the trainer says "OK," claps, and again guides the dog to the left side, steps away as before, and encourages the dog to follow along at the left side until the trainer once again stops and prompts the dog to sit or steps back calling the dog's name or smooching to encourage it to turn and come. As the dog turns, a click is delivered and, as the dog moves in the direction of trainer, the vocal signal "Come" is spoken in an enthusiastic command tone as the right hand is flicked to the side. As the dog reaches the hand, the bridge "Good" is spoken and the hand is opened. This pattern is repeated several times, establishing an associative link between coming and reward.

Orienting Response

Attention control is of great utility in dog training (see *Attention and Impulse Control*). Obviously, for a dog to be trained, it must pay attention to the trainer's actions. A dog's attention can be attracted by employing various unconditioned or conditioned diverters, evoking surprise and competing interest, e.g., throwing a ball or presenting a conditioned stimulus previously paired with food (e.g., a whistle). In addition, most dogs quickly orient toward unfamiliar or out-of-the-ordinary stimuli. By calling a dog's name just prior to presenting a potent diverter or disrupter, the name is gradually conditioned as a generalized orienting stimulus. As the dog learns to respond to its name by orienting its attention toward the trainer, its name can be used to interrupt distracted behavior and to serve as a preparatory cue for commands. For example, in the case of training a dog to come, its name is used to evoke an orienting response, followed by command cue "Come" and additional prompting and encouragement, as necessary. Since the distracting environment itself is rewarding, releasing the dog after it comes serves to further reinforce the habit of coming when called. Consequently, when the dog reaches the trainer, it is immediately rewarded and released with an "OK" and hand clap. As the result of repeatedly calling and releasing the dog after it comes, it gradually learns to expect that coming not only results in a food reward but also results in another opportunity to explore the environment.

A useful attention-controlling strategy is to pair a whistle or squeaker sound with treats, feeding times, and just prior to other strongly reinforcing events (e.g., access to special toys and announcing owner homecomings). Gradually, the dog learns that the squeaker announces a moment when a food reward is likely to be forthcoming. The whistle is not a recall signal, although it may be conditioned to function as one; rather, it is an establishing operation signifying an opportunity to obtain a variety of possible attractive outcomes if the dog simply orients and takes it. If the dog does not come, no matter; it has simply lost the opportunity to obtain the reward. Additional orienting control is established by bridging the orienting response with a clicker. The click is delivered just as the dog begins to orient to its name, a smooch, or a squeak. The click is followed by a flick of the hand to the right and the delivery of a variable reward

conducive to surprise. For example, varying the size and type of the reward given to the dog can magnify the effect of this training.

Attending Response

Whereas orienting behavior is momentary and strongly affected by reflexive mechanisms, attending behavior occurs with some duration over time and is more directly controlled by instrumental contingencies of reinforcement. Teaching dogs to look up and hold eye contact is an important aspect of dog training and socialization. Making various nonsense sounds (e.g., clucking or lip noises of various kinds) helps to get a dog to look up into the eyes. The moment the dog makes eye contact, the response is bridged and reinforced with an affectionate smile, sweet talk, and a treat. The clicker can be used effectively to help shape attending behavior in dogs that resist making eye contact. Once eye contact is establish, the duration of the response can be gradually increased until the dog is holding it for a second or two. As the dog learns to look up and make eye contact in response to a smooch or cluck sound, its name can be paired with the orienting stimulus. Calling the dog to come and sit and look up briefly before rewarding and releasing it promotes a valuable pattern of control (Figure 1.11). In the case of highly distractible dogs, a squeaker-clicker combination can be useful for capturing and shaping the dog's attention. The squeaker device (extracted from a squeaker bulb) is inserted into a hole drilled into the clicker (see Figure 1.9). A wide range of sounds can be made with the squeaker, minimizing the effect of gradual habituation to the sound. As the dog turns, the clicker is pressed, thereby reinforcing the orienting response. This procedure is repeated under varying conditions of distraction until the dog is quickly orienting to the sound of the squeaker, at which point its name can be paired with the sound.

Targeting and Prompting

Most training activities make use of body or hand movements to prompt, lure, or target the dog's behavior. Training a dog to orient and follow the trainer's body and hand movements is an important aspect of basic training, providing a foundation for more complex and advanced control efforts. Training the dog to take food from the right hand and then requiring that it follow the hand as a contingency for getting the reward helps develop a targeting response to the hand. The dog is trained to target on the hand by holding the right hand at the dog's eye level so that it either looks at the hand (in the beginning) or actually touches it with its nose before the behavior is bridged and rewarded. As the dog learns to orient and follow the hand, the targeting behavior is shaped through successive approximations until it is a strong and reliable response. The attractiveness of the hand as a target can be enhanced by rapidly flapping the first two fingers like beating wings—a technique referred to as a birdie lure. Training the dog to target on the hand allows the trainer to guide or position it without needing to use physical prompts. Targeting provides a rapid means to facilitate the response as well as

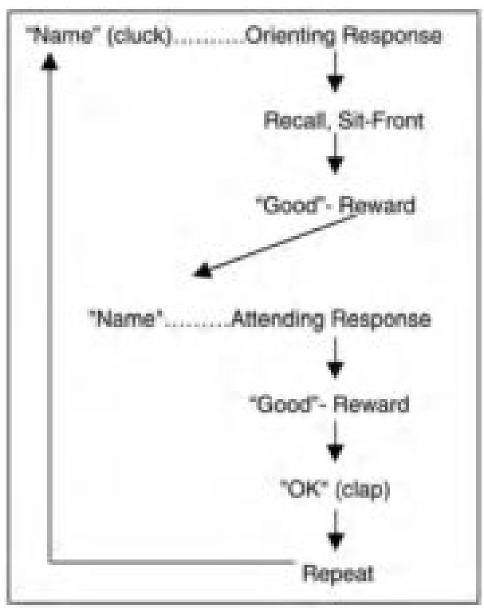

FIG. 1.11. Attention-training sequence: orienting response, recall, sit, attending response, and release.

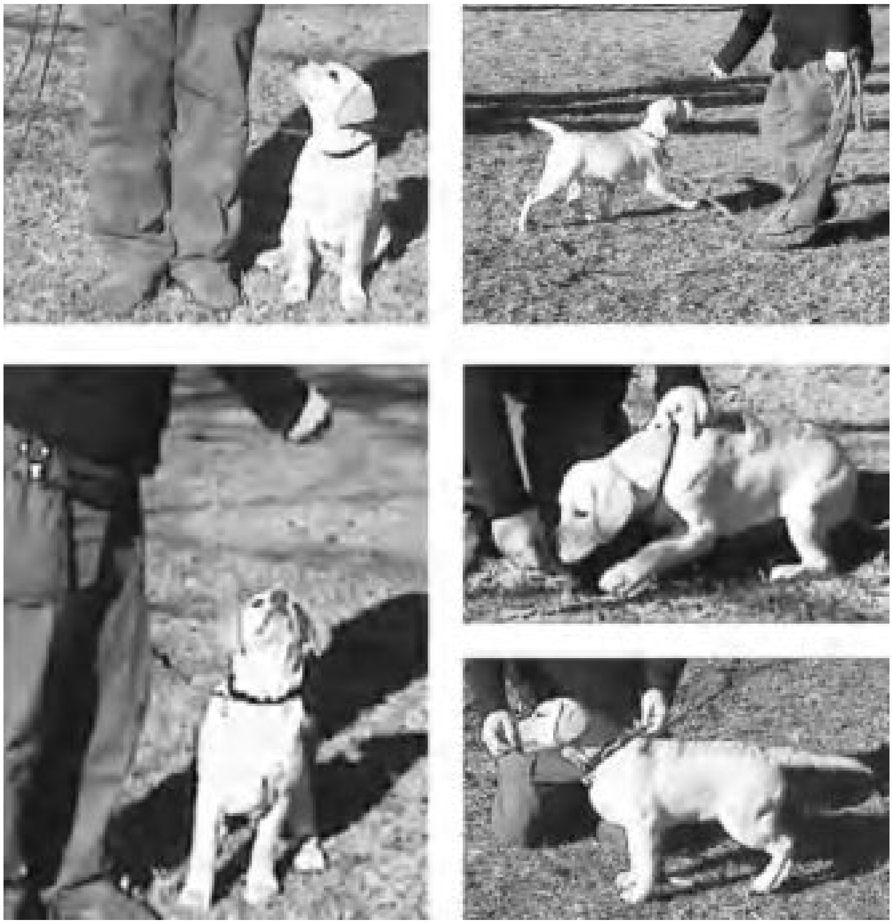

FIG. 1.12. Puppy targeting and prompting.

developing a hand signal to control it (Figure 1.12). Training the dog to reliably orient (turn toward the trainer on signal) and target on trainer's body movements and gestures is the most important objective of basic training.

As the dog's targeting behavior improves, hand and body movements can be used to guide and prompt it into various positions. For example, teaching a dog to sit is easily accomplished by moving the right hand slowly over the dog's head. As the dog follows the trajectory of the hand, there is a natural tendency for it to sit. If the dog jumps up at the hand instead of sitting, the hand can be repositioned to discourage jumping, or the trainer can simply step on the leash to prevent the unwanted jumping behavior. The bridge "Good" is presented just as the dog begins to sit, with the food reward and affectionate petting delivered as the dog completes the action. At the conclusion of the trial, the dog is released with an "OK" and hand clap, guided to the left side, and walked out several steps before the trainer steps back and calls the dog to come again, whereupon it is prompted with the hand signal to sit and is appropriately rewarded. This pattern is repeated until it is performed fluently. Once the dog is sitting reliably in response to the prompting of the hand signal, the vocal signal "Sit" is paired with the action. After several pairings in which the word "Sit" is spoken just before

the hand signal, the vocal signal alone will prompt the sit response. At this point, the hand signal can be progressively delayed or minimized, with the dog learning to respond to the vocal signal alone, gradually enabling the dog to sit in response to the vocal signal alone. If the dog fails to sit when the vocal signal is given, the signal should not be repeated; instead, the hand signal is used to prompt the action. A fairly reliable measure of a dog trainer's understanding of the process and skill can be calculated by the number of times she or he repeats vocal commands. Later on, while training the automatic sit, both vocal and hand signals are delayed or minimized, so that the dog learns to sit without aid whenever the trainer comes to a stop while the dog is heeling or at other times requiring that it sit automatically (e.g., sit-front and starting exercise). Generally, for routine training purposes, it is better to continue giving the dog a combined vocal and hand signal, since the latter helps to progressively strengthen the dog's responsiveness to the former. After rewarding the sit response, the dog is required to wait to be released with an "OK" and hand clap. If, at any point in the process, the dog appears confused or quits, the trainer should go back to the hand signal or review a previously successful step (e.g., "Come" or "Good" conditioning, attention training, and targeting on the hand) and begin again.

As the dog is guided around to left side at the conclusion of the come exercise, it can be prompted to sit at the trainer's left side and be rewarded. After a brief moment, the trainer steps off and encourages the dog to follow along with the vocal signal "Come one," sweet talk, smooches, or slaps on the leg. As the dog orients toward the left side and continues there for a few steps, the trainer stops and prompts it to sit. If the dog runs out ahead, the trainer should turn into an opposite direction while making smooches, slapping the left thigh, or crouching down to encourage it to follow along in the new direction. As soon as the dog responds, the bridge and reward follow. If the dog moves off to the left, the trainer turns to the right and encourages the dog to follow along. If the dog lags behind, the trainer picks up the pace with gentle encouragement, perhaps bouncing a ball, making smooch sounds, or crouching down momentarily. Whenever the dog comes close to the trainer's side, the bridge and treat are delivered. After a change of pace, a turn, the dog's close walking is bridged (e.g., click) and it is prompted to sit at the trainer's left side, rewarded, and the sequence is repeated. With every successful walk-sit sequence, appropriate bridging and rewards follow. While training the dog to come along and walk close by, the trainer can mix in come and sit-front training as together with orienting and attending sequences.

Most dogs can rapidly learn to lie down from the sit. The task is usually introduced with the trainer crouching down or sitting on the floor and luring the dog down with the right hand. In some cases, the behavior may need to be shaped through successive approximations, starting with a downward bobbing movement of the dog's head, a reaching movement toward the floor and, finally, lying down. As the dog learns to follow the hand into the down, the vocal signal "Down" is paired with the hand signal. The dog should also learn to sit from the down and stand from the sit. Using a hand-targeting strategy helps the dog to learn both of these movements easily. If the dog ignores the hand, the birdie lure can be used to attract its attention. Once the dog is lying down, the trainer moves the right hand upward in front of the dog's nose, causing it to follow the movement. Similarly, the dog can be prompted in the stand position by putting the right hand in front of the dog's nose and drawing it away, thereby causing it to stand. This basic cycle of exercises (sit, down, stand, and sit) can be performed with a toy as a lure and using an opportunities to tug and fetch as a reward. As the dog masters each movement, an appropriate vocal command is paired with the hand signal. In the case of resistant dogs, a food lure (usually a small biscuit) is used to break the ice. Luring with food can be very problematic, however, and should only be used to get a response that is not likely to happen in a timely way otherwise. After two or three luring trials, the biscuit should be hidden in a closed hand and finally faded completely out.

Excessive reliance on food baiting and luring tends to produce "chow hounds," that is, dogs that will only work with the direct promise of a food reward in sight.

Stay Training

Once the dog is readily orienting, coming, sitting, and looking up on signal, the sit-stay exercise is introduced (see Appendix A). Many aspects of the stay module have already received preliminary training. For example, after coming and sitting, the dog has been required to wait a moment, steady its attention, and make eye contact as a contingency of reinforcement and release. Once these preliminaries are under control, it is an easy and natural step to train the dog to stay for longer periods and at greater distances from the trainer. The first criterion is to have the dog hold a sit-stay for a progressively longer and then variable duration before the behavior is reinforced. The variable duration of the stay response provides an interesting source of prediction error (surprise) with which to strengthen waiting and attending behavior. Releasing the dog sooner than expected relative to a standard expectancy provides a surprise and reward that can be used to steady attending behavior, especially if the dog is prompted to make eye contact in advance of being released. Similarly, vary the amount of time that the dog waits before being let outdoors, to come up on furniture, to receive a favorite toy, to be permitted to jump up, and so forth can help to strengthen waiting strategies and improve delay of gratification. The next criterion is staying as the trainer steps away a step or two. As the trainer steps back, a stay flag is presented, which is formed by extending the right arm in front of the body at chest level, with the right hand held out. The fingers should be held together and pointed up, with the palm facing the dog.

Initially, the dog is required to hold the sit-stay position for a brief period before it is rewarded. The best stay performances are built up carefully and slowly in the context of attention training. Ideally, the dog should maintain eye contact with the trainer as he or she steps back and again as the trainer returns to the dog. The dog should also maintain steady eye contact just before being released. The release should be treated as a trained response that is brought under the control of play activities (e.g., tug and ball play). During the early phases of stay training, it is important that the trainer return to the dog instead of calling the dog to come at the conclusion of the sit-stay period. If the dog happens to break the stay position, it is lured or guided back by leash to the original spot and prompted to sit. Breaking the stay during early stages of training should be treated as a mistake of judgment on the trainer's part rather than an act of obstinacy on the part of the dog. When the dog breaks the position, it is best to simply try again at an earlier and more successful step. With every successful stay performance, the dog is rewarded (food, petting, praise) and released momentarily between trials, often engaged in play. Ideally, the process should proceed with a minimum of errors, but, in practice, learning from mistakes can also be very beneficial, so long as it does not result in excessive anxiety or frustration. The goal of sit-stay training is to enhance impulse control, not by anxious inhibition, but rather by training the dog to focus and relax. Patience in the process of training the dog to sit and stay is rewarded later on.

The most common problems encountered during the early stages of stay training involve impulsive behaviors associated with distractions. These motivations can be turned to the trainer's advantage by making access to them contingent on the dog waiting or staying first. An affirmative way to view distractions is to consider them as potential rewards not yet under the trainer's control. In the case of some highly excitable dogs, training efforts may be impeded by such distractions. Normally, distraction-dense environments are avoided until a dog's attention and impulse-control abilities are adequately prepared to meet the challenge.

Play and Controlled Walking

The controlled-walking pattern is shaped through successful approximations. The easi-

est way to introduce the walking behavior is through play. The first step is to encourage the dog to chase and retrieve a stick or ball. As the dog becomes excited about the toy, it is held in the right hand and used to guide the dog around to the left side. If the dog goes too far out in front, the trainer turns about while making smooch sounds and tapping a stick to the ground and encouraging the dog to follow along. When the dog returns to the trainer's side, the stick is tossed for the dog to retrieve and to come back for a tug and treat in exchange for releasing it. After a brief tug, the dog is prompted to release the stick and is lured as before to the starting position at the trainer's left side. The stick is held diagonally in front of the trainer, just out of reach of the dog, and the trainer steps off on the left leg, whereupon the stick is tapped against the front surface of the thigh, accompanied with clucking or smooching sounds to attract the dog's attention. With the dog walking close on the left side, the bridge "Good" is delivered, and the trainer comes to a stop and prompts the dog to sit by waving the stick in an upward direction over the dog's head, causing it to sit. As the dog sits, it is praised, treated, and given another opportunity to fetch the stick. Instead of using a stick, a tennis ball with handle can be used in a similar way. Gradually, the dog is required to hold the sit for longer durations before the stick is thrown. For some insecure dogs, a food lure or licking stick (e.g., a yardstick with peanut butter or crème cheese smeared on it) can be a helpful means to introduce the concept of walking close at the left side. The food lure or licking stick is held a few inches in front of the dog, allowing the dog to lick occasionally while walking or after being prompted to sit.

Clicking and Controlled Walking

Another very effective way to introduce attentive controlled walking is by using a clicker. While walking the dog on a leash, a click is delivered so long as it remains on the trainer's left and walks close by without pulling. With each click, the trainer stops and prompts the dog to sit, whereupon the trainer says "Good" and the treat is delivered. Initially, the click-and-treat procedure is repeated every few steps, but gradually the dog should be required to walk without pulling for longer periods before delivering the bridge and reward. If the dog pulls, its name is called as the slack of the leash is let go; alternatively, a squeaker is sounded to get the dog's attention and cause it to turn around. Just as the dog turns in response to its name or squeaker, the click is delivered and the dog encouraged to return to the trainer's left side, whereupon it is prompted to sit and is given a treat. The combination clicker-squeaker is convenient for such training. Under distracting conditions, repeated and sustained reinforcers involving several small pieces of food, petting and massage, play, and vocal encouragement may be helpful to keep dogs focused and on track.

On-leash and Off-leash Practice

It is important that trainers practice the above tasks with puppies or dogs both on and off leash. Although an experienced trainer can carry out initial training efforts effectively with a dog off leash, it is usually best to work the puppy or dog on leash or long line and then gradually introduce off-leash elements as the various necessary skills are mastered. Backup leash control is particularly important in the case of dogs and puppies receiving training to curb social excesses and impulsive household behavior. Although beneficial in the early stages of training, overreliance on the leash control may cause both the trainer and dog to become dependent on it, thereby making it much more difficult to fade it out later. Reducing dependency on the leash requires that the trainer master skills needed to control a dog with vocal signals and gestural prompts alone. Also, during training periods when the leash is off, the trainer gets a more accurate picture of what the dog actually knows as the result of training. Control is meaningful only to the extent that it can be exercised both on and off leash. When the dog is worked off leash, mental notes should

be kept about areas of training that may require additional work on leash.

WALKING ON LEASH

A dog's excessive pulling and lunging while on leash is perhaps the most common reason for owners to seek training help. While a confident and well-trained dog is an object of owner pride and affection, an impulsive and rambunctious one can rapidly become a source of tremendous frustration and public embarrassment for the owner (Sanders, 1999). In some cases, the owner is physically unable to walk the dog because of excessive pulling and various misbehaviors that occur while on leash, further complicating matters by giving rise to deficiencies associated with inadequate exercise and outdoor stimulation. Consequently, such dogs may become progressively difficult to handle and manage, setting the stage for the development or exacerbation of behavior problems associated with excessive activity and impulsiveness. Training dogs to walk properly on leash is vital, not only to develop and augment attention and impulse control, but to strengthen the leader-follower bond, as well. The dog that walks in close cooperation with the trainer's pace and direction takes each step and turns in acceptance and deference to that person's role as leader. Training the dog to walk properly and skillfully on leash provides a foundation for a more positive and mutually rewarding experience for both the person and the dog.

Even though pulling into a leash results in physical discomfort for a dog, forcefully holding the dog back appears to increase rather than reduce the magnitude of its pulling efforts. Pavlov (1927/1960) postulated a *freedom reflex* to help explain the dog's oppositional response to restraint. Reflexive opposition to restraint has biological significance, since, as Pavlov points out, "it is clear that if the animal were not provided with a reflex of protest against boundaries set to its freedom, the smallest obstacle in its path would interfere with the proper fulfillment of its natural functions" (12). A related phenomenon, thigmotaxis (Gk, *thigma* or touch), refers to reflexive adjustments associated with taction, but should be distinguished from Pavlov's oppositional freedom reflex. Thigmotactic adjustments are divided into two categories, depending on whether a dog moves toward contact (positive thigmotaxis) or moves away from contact (negative thigmotaxis). Common examples of positive thigmotaxis include the rooting reflex or the tendency of fearful dogs to lean on the owner's body as a source of security. Physical opposition may also excite positive thigmotaxis, but since the dog's efforts at such times appear primarily intended to oppose the physical control, it may be more appropriate to refer to such behavior as an opposition reflex rather than thigmotaxis. Perhaps the concepts of positive and negative thigmotaxis should be reserved for describing contact behavior occurring at times when seeking comfort or safety rather than frustrated behavior associated with physical force or barriers.

When confronted with physical forces and obstacles that thwart their freedom of movement, a dog reflexively responds with commensurate oppositional behavior aimed at countering their effects. For example, the harder the owner pulls back on the leash, the more the dog will tend to pull forward (forge) against it. Similarly, if the dog is pulled forward, the dog will tend to compensate by pulling back (balk), as opposition reflexes are elicited. The motivational effect of opposition is frustration. The typical behavioral response to frustration is potentiation and persistence of oppositional behavior. The amount of oppositional effort expended by the dog depends on a number of factors, but especially upon the value of attractive incentives toward which the pulling action is directed. The primary goals of the activity appear to be the optimization of drive-activating stimulation and control of the direction and pace of the walk. Few dogs find pulling into the leash sufficiently aversive to stop doing so, even in cases where their breathing and circulation are affected by the activity or where obvious discomfort is involved.

Although holding the dog back briefly is not harmful, passively holding the dog back by a dead leash for extended periods to break its will to pull (freedom reflex) is a highly questionable practice. The theory promulgated by proponents of the method is that the

dog will eventually cave in and defer to passive restraint, but actually such stimulation often evokes a persistent oppositional reflex causing the dog to continue pulling despite significant discomfort and physiological distress. Instead of discouraging pulling, such restraint often does little more than increase frustration and oppositional behavior. The procedure has become increasingly popular as a means to discourage pulling, partly because of its simple theory and application—any ambulatory person with a strong back and arms can stand like a post and hold a dog back and thwart its oppositional pulling efforts. For such methods to have a chance of success, they require a great deal of consistency and perseverance. Unfortunately, however, ordinary dog owners are often woefully deficient on both scores and will frequently ignore pulling efforts rather than consistently perform the rather tedious ritual of waiting until the dog stops pulling before taking a step forward. As a result, the pulling behavior may never get better, but instead may grow significantly worse as the result of frustration-related enhancement and intermittent negative reinforcement. Finally, given the availability of effective leash-training alternatives that work quickly and reliably to discourage pulling, letting a dog pull on leash until its will to pull is broken (i.e., the opposition reflex is fatigued) or until it becomes exhausted makes little sense. In cases where an owner is unable or unwilling to assert appropriate leash control, a halter can be introduced to passively control pulling excesses.

Not only are such leash-breaking methods questionable with respect to efficacy, they risk producing significant harm if performed on dogs that persistently pull while being exercised. Pulling continuously on a leash can impede efficient ventilation and blood circulation, thereby hampering the dog's ability to circulate and cool arterial blood before it enters the brain. While a dog is walking or running, arterial blood rapidly heats up and needs to be cooled to prevent brain damage associated with thermal stress. Blood entering the brain is cooled by passive thermal exchange between arterial and venous vessels, whereby heated arterial blood is cooled by venous blood draining from the nose and mouth of the dog (Baker and Chapman, 1977). As the result of holding a dog back by a collar around its throat, both ventilation and venous blood flow are variably obstructed, depending on the force of pulling and the sort of collar used to restrain the dog. Venous blood flow is more easily obstructed by external pressure on the neck than is arterial flow, which passes through the neck under pressure and is partially protected by the spine (vertebral artery). The net result is that heated arterial blood continues to pump into the brain while decreased ventilation and obstructed venous blood flow hamper its efficient cooling—a physiological condition capable of producing significant harm or discomfort to dogs laboring under adverse weather or exercise conditions. Intentionally allowing impulsive or oppositional dogs to pull into a dead leash is tantamount to *horizontal hanging*—a procedure that is difficult to justify as a humane means to stop or control excessive pulling by dogs.

Most dogs exhibit intense preparatory arousal whenever the owner gets the leash to take the dog for a walk. In the case of a pulling dog, the appearance of the leash functions as an establishing operation, motivationally preparing the dog to pull and to obtain reinforcement as the result of such behavior.

Dogs that engage in excessive pulling are often inordinately attracted to environmental stimuli and engage in excessive exploratory and stimulation-seeking activities. In addition, such dogs are often hyperactive and may exhibit marked impulse-control and attention-related deficits that require training efforts designed to enhance attentional focus and executive restraint. Various diverter-type and disrupter-type stimuli are employed to interrupt pulling and to refocus a dog's attention. A squeaker-clicker combination can be used to get and then reinforce attention and orientation toward the trainer. Giving such dogs an opportunity to engage in vigorous ball play before going for a walk can help to reduce pent-up energy fueling excessive pulling behavior. Moving from the play situation to a long line and then to a short leash appears to make the transition easier for many dogs because it helps to reduce oppositional

reactivity and impulsive behavior when on leash.

Leash Handling

There is a certain amount of truth to the adage "Master the leash, master the dog." Before describing the basic techniques of leash training, leash-handling lore and methods need to be reviewed briefly. There are many ways to hold and handle a leash. One of the best methods for routine training purposes is first to place the thumb through the leash loop and then close the hand around it, forming a fist (Figure 1.14A). A more secure control is obtained by passing the hand through the loop and bringing the leash over the top before gripping and setting the trigger (Figure 1.13). Next, in order to take up and grip the slack of the leash, the first two fingers are extended, with the third and fourth fingers flexed firmly on the leash handle (the *grip*). The shape of the hand at this point looks like the Scout salute. A variable length of the leash is taken up into a single fold and held between the thumb and the index finger (the *trigger*) (Figure 1.14F and G). When walking a dog on a slack leash, the leash is held in the left hand. When practicing or performing formal exercises, however, the leash is dressed in the right hand. The leash is dressed with the dog in the starting position, and both arms are fully extended and relaxed. The *standing end* and slack of the leash is held in the right hand while the *working end* runs slackly down and across the trainer's left leg to the dog sitting at heel (Figure 1.14G).

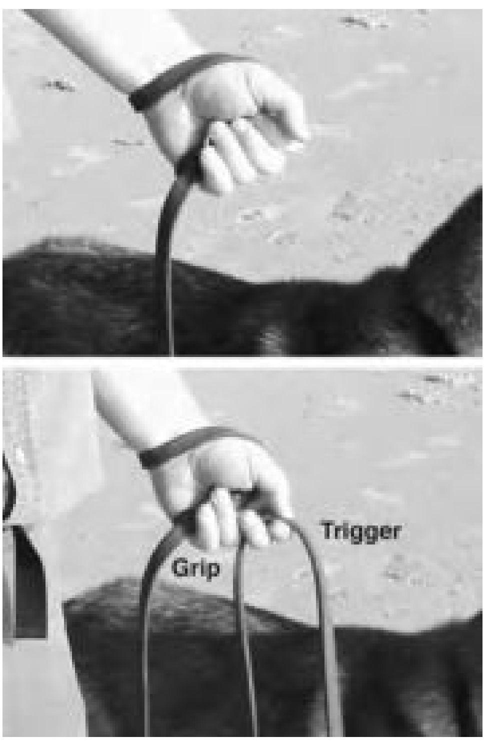

FIG. 1.13. Secure leash control.

In addition to holding and dressing a leash, trainers should be familiar with three leash manipulations: breaking, opening the leash, and changing leash hands. Breaking prevents the leash from slipping through the fingers. Many styles of leash braking are used in dog training. The most common brake is set by taking the working end of the leash with the left hand and wrapping it over the left thumb and then firmly closing the hand over the leash (Figure 1.14D). Thumb brakes are particularly useful when working with large breeds or when using nylon leashes that tend to slip through the hands. The leash is opened by taking up the working end with the left hand and setting a thumb brake before realeasing the slack held in the right hand. As the brake is applied, the left hand draws the leash open, thus freeing the right hand (leash still hung from the right thumb) to present hand signals or treats (Figure 1.14D). Besides opening the leash, trainers should know how to change leash hands properly. There are two basic ways to change leash hands. When passing the leash between hands, both its working and standing ends are gripped together just beneath the handle (Figure 1.14E). As the right hand lets go, it leaves a glovelike shape impressed into the leash fold and handle. The leash is dressed again by regripping the handle and the fold of slack as previously described. Another method for changing leash hands involves moving the thumb upward and causing the leash handle to shift up (Figure 1.14A–C). Now, the opposite thumb can hook the handle and take up the standing slack in a single fold. When the dog is located in front of the trainer or at some distance away, the leash is exchanged in a similar way between hands by the thumbs, and the standing slack is taken up as needed. The leash

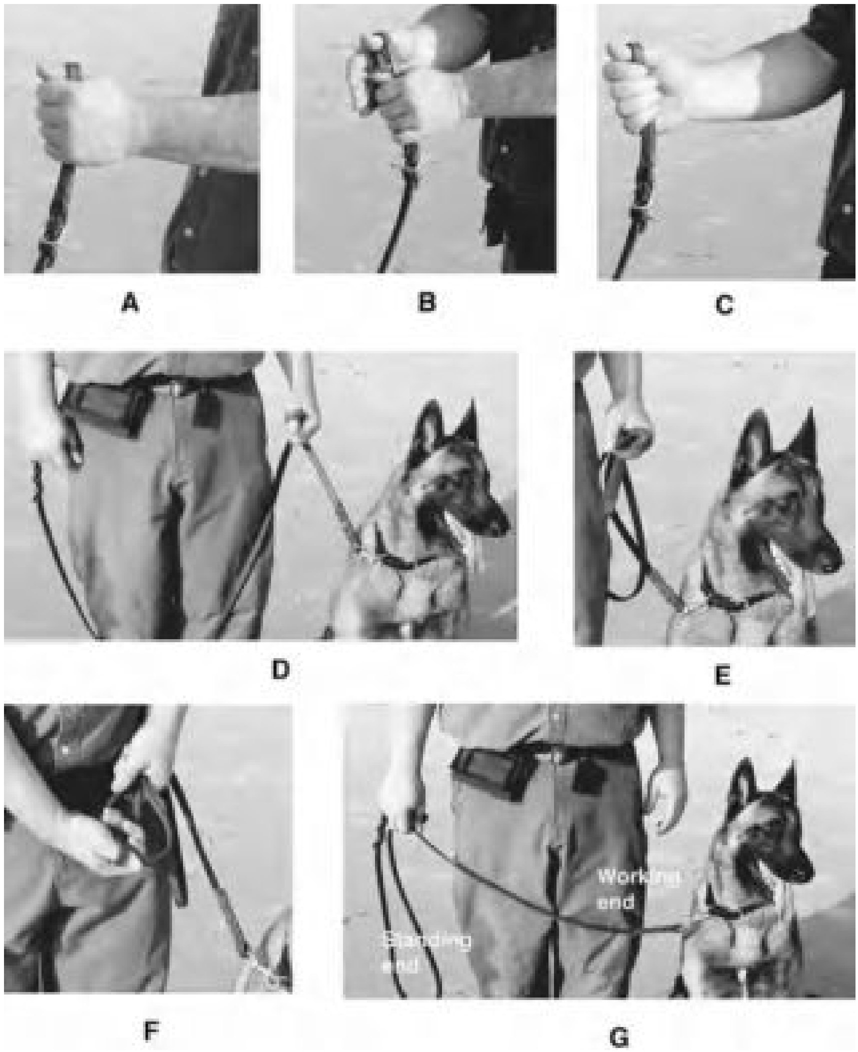

FIG. 1.14. Leash handling: basic leash control **(A–C)**, opening the leash and brake **(D)**, changed leash hands **(E)**, setting the trigger **(F)**, and dressed training (starting position) **(G)**.

should never tangle to the ground—it should always have a presence of control but never be taut. Leashes should never be knotted, except as needed to form temporary looping for hip-hitching or coupling techniques in which two leashes are tied together to control a brace of dogs.

Leash-training Techniques

Choosing the appropriate method for a dog's needs is of tremendous importance. Some dogs may require very little in the way of directive or physical prompting, whereas others will require more forceful handling strategies. Four techniques are generally used, depending on a dog's needs:

1. Long-line training involves the use of reward-based attention-control techniques and avoidance cues ("Easy" and "Stay") together with stepping or tamping on a long line dragging on the ground.
2. Slack-leash training involves using an abrupt release of leash slack to simultaneously capture the dog's wavering attention and

deter future pulling with appropriate anchor and opposing thrust movements.

3. Hip-hitch training is based on a response-blocking strategy in which forward movement is interrupted by stopping, back-stepping, and otherwise preventing the dog from moving forward until it stops pulling and momentarily turns its attention to the trainer.

4. Halter training prevents pulling by using a halter-type collar and stresses positive reinforcement to shape attention and walking without pulling.

Working the dog outdoors among distractions is a major transition that often requires the addition of directive methods of control. The preliminary work done indoors and in the backyard has taught the dog what is expected of it through a reward-based training system, but knowing what to do and possessing a reliable ability to do it are two very different things. Although the dog may know how to sit or lie down and stay on signal, it may not be willing to perform the tasks as obedient acts on command, especially in situations where it would prefer to do something else. In such cases, it may be necessary at times to constrain the dog to perform the required behavior by means of directive prompting. Most importantly, however, as noted earlier, the social limit around pulling on the leash is of vital importance. The leash represents a physical extension of human will, which when properly introduced and used provides a dog with a valuable source of guidance and instruction. As such, the dog must first learn to defer to the leash and actively follow its directive movements and prompts without hesitating or resisting. A central goal of slack-leash training is to condition a dog's attention to respond to the leash so that it actively follows its guidance, thereby facilitating reward-based training efforts while minimizing exposure to leash corrections.

There are three ways that a dog is walked when outdoors, depending on the control needed at the time: slack leash, controlled walk, and heeling. Slack-leash training only entails that the dog not pull while on leash. During slack-leash walks, the dog is permitted every *reasonable* liberty, such as sniffing about, moving from one side to the other, lagging behind, or forging ahead. The only liberty forbidden to the dog is pulling or lunging into the leash. Controlled walking adds the criterion of walking at the left side without forging beyond the point where the dog's hip aligns with the trainer's left leg. Walking at heel is an entirely different matter. Heeling is a highly structured and formal activity requiring that the dog walk in a precisely defined position at the owner's left side without sniffing or moving about. Heeling is a demanding activity requiring that the dog focus its attention on the trainer's every movement. Although restrictive and highly formal, walking at heel should not appear overly constraining or mechanical. Instead, an appearance of elegant harmony between the owner and dog should cause observers to reflect on its meditative qualities. In fact, good heeling is a meditation, bringing both dog and trainer into an attentional nexus of single-mindedness on the moment. This sort of effort requires tremendous concentration and can been done only for short periods in the beginning, with the dog heeling for longer stretches of time as its ability to focus improves with maturity and training. On an average walk, the dog should only be brought to heel periodically and released, with 90% of the walk enjoyed at ease but without pulling.

Long-line Training

Highly active dogs can be first exposed to leash control on a long line. A 30- to 50-foot length of quarter-inch braided white nylon rope is fitted with a knotted hand loop and a limited-slip collar (Figure 1.8). Alternatively, the long line (soft nylon webbing) can be fitted with a knotted fixed-action halter. The long line can be either held in hand or allowed to run freely on the ground. The long line is controlled both by tamping or stamping actions (foot braking) to limit pulling behavior and to gather and focus the dog's attention. Whenever the dog rushes beyond 10 to 15 feet away and ignores other established orienting and attention-controlling signals, the long line is tamped or stepped on and the dog prompted to return to the trainer, required to wait briefly, and released

again. In addition to a free-running procedure in which the long line is let to drag on the ground, a hip-hitch and control lead are used in combination to refine control efforts. Whereas the hip-hitch provides a reliable means for blocking and countering pulling efforts, the control lead gives the trainer the ability to abruptly block and guide the dog's behavior with directive prompting. An added benefit of the hip-hitch is that it frees the trainer's hands to deliver rewards and manipulate bridging devices. During long-line training, the dog is called by name to get its attention in anticipation of tamping and stamping actions. "Easy" is paired with the tamping action, whereas a firmly spoken "Stay" command is paired with the abrupt stamping on the long line to block lunging. As the dog is brought to a halt, the trainer either goes to the waiting dog or recalls it before rewarding and releasing it to continue the walk. During long-line training, the dog is periodically called by name together with an orienting prompt (e.g., squeaker, whistle, or clap), as necessary, clicked as it alerts and begins to turn its head, and is recalled with the vocal command "Come" and hand signal. Upon reaching the trainer, the recall is bridged with "Good" and a variable reward, whereupon the dog is immediately released with "OK" and hand clap. In addition to food rewards, the dog is offered tug and ball-play activities while worked on the long line. A balking or lugging dog is encouraged with slaps on the thigh, crouching, change of pace, and enthusiastic voice and hand gestures paired with "Hurry up."

Slack-leash Walking

With the prospects of a walk, most dogs become excited and active, an enthusiasm that spills over into the walk itself. The first step, therefore, is to organize the various preliminaries to a walk in a way that is conducive to improved impulse control. Obtaining noncontingent treats at such times can help to modulate a dog's excitement by way of diversionary appetitive arousal and incompatible establishing operations. As the dog's interest turns toward the trainer in hopes of getting more treats, various behaviors that have been previously conditioned with food reinforcement are more likely to occur, making control at such times easier. The leash should not be put on the dog until the dog settles down and sits or stands quietly, thereby making the leash a contingent reward based on compliance. Further, the dog should wait at the door briefly before being released. By using a well-conditioned orienting stimulus (squeaker), the dog's attention can be turned to the trainer and bridged (click), whereupon the dog is guided from the door before the vocal bridge ("Good") and food reward are presented. The dog is gradually trained to back away from the door by calling to it "Back" before opening the door. In some cases, tossing a treat back as the door is opened will help to encourage the dog to turn or back away when the door is open. Preliminary reward training at the door should be integrated as a routine and prerequisite to going for a walk. If the dog bolts through the door, it is brought back inside, and the procedure is repeated. Directing the dog away from the door with the leash as the door is opened can be helpful. In addition to backing up as the door is opened, the dog should learn to wait in the doorway for a release signal (e.g., "OK") before exiting the house. The goal is to train the dog to back up as the door opens and then to wait at the doorway under the vocal signal "Wait," until it is released with an "OK." These compliant behaviors are gradually brought under the control of the rewarding opportunity to go for a walk.

The foregoing procedure is repeated until the dog defers and waits quietly before being allowed to go through the door. In the case of highly motivated dogs, exclusionary time-outs (TOs) can be used to reduce preparatory arousal associated with going for a walk. The reprimand "Enough" is spoken in a firm tone and the dog put outside for 30 seconds with the leash pinched in the doorjamb. The TO procedure is repeated until the dog calms down and defers to owner control efforts, whereupon reward training is reinstated. The TO procedure not only reduces preparatory arousal and undesirable behavior, it also makes it more likely that the dog will hesitate and back away as the door is opened. If, despite these training efforts, the dog charges

through the door, the leash is pulled back and the door is closed on it, leaving the dog in TO on the other side. This procedure is repeated until the dog hesitates at the door and waits for the release to leave the house.

Once outdoors, pulling into the leash is handled with appropriate countermovements and directive prompts. The strength of such prompting is matched to the dog's effort to pull and its sensitivity to such stimulation. The strength of directive leash prompts is determined by the dog's forward momentum. The dog can be fitted with a limited-slip collar, strap collar, or harness, depending on the specific needs of the dog and owner. During the slack-leash walk, the leash is held in the hand closest to the dog. Approximately two-thirds of the leash is taken up in a single fold, referred to as a *bight,* and held between the thumb and first two fingers of the left hand (see the aforementioned directions for holding a leash). The properly dressed leash always has at least two points of slack (or life) in it. If both the standing and the working slack are lost, the leash is dead, and a small bight of standing slack (life) must be wrestled up before an effective leash prompt can be made. Whether on a slack-leash walk or while heeling, a small bight of the standing end of the leash is always kept in hand. In addition to standing slack, some amount of slack is kept in the working end of the leash. In some cases, a leash is held with a *bight and pinch* during controlled walking (Figure 1.15). A *pinch* is a small amount of leash slack that is taken up and held between the index finger and thumb and released as a warning in advance of dropping the standing slack. When the working slack is pulled out of the leash by the dog, the standing slack is released as both hands are brought together on the handle as one holds a bat. In the same instant, the trainer takes one step back on the left leg and firmly anchors the leash just in front of his or her belly. Alternatively, if the leash is held in the right hand, the trainer steps back on the right leg before bracing against the dog's forward momentum. Sidestepping to the left or right of the dog's line of movement can help to minimize the amount of force needed to disrupt its forward movement and turn it

Fig. 1.15. Bight and pinch provides a third point of life in a leash.

about. Coordinating the movements of the body into one brief, unified thrust against the dog's forward momentum generates the leash prompt—not jerking, yanking, or pulling against a dead leash. If the dog charges at an awkward angle, the trainer should follow and align with the dog's direction of pulling before releasing the standing slack, anchoring the leash, and thrusting back. If the prompting action is properly applied with sufficient force, the dog will turn toward the trainer. As the dog turns, the trainer should immediately encourage it to come back and guide it to turn about at the trainer's left side, where it is prompted to sit or stand and briefly wait before being released to walk ahead again. Another variation of this method involves using a hip-hitch and stopping whenever the dog pulls for a count of 3 before the leash slack is dropped and the trainer steps back and anchors the leash, as described previously. Again, just before the standing slack is released, the owner calls the dog's name. This variation appears to be easier for some dog owners to carry out, allowing them to take one step at a time. The slow count is gradually varied so that it is delivered sooner (e.g., sometimes as soon as the dog pulls on the leash) and later than expected, thereby producing prediction error conducive to enhanced attention and avoidance of pulling.

As the result of the foregoing procedure, the dog rapidly learns to anticipate the leash prompt whenever the standing slack is loosed abruptly from the trainer's hand. The dog also learns another important lesson: the prompting action can be avoided by responding quickly and slowing down just as the trainer lets go of the leash slack. Once it is evident that the dog understands these connections, the dog's name is called just before the slack is dropped, thereby bringing the new behavior under additional stimulus control and enhancing the nominal orienting response. Now, as the dog pulls, its name is called and the leash slack is dropped, thereby causing the dog to hesitate and turn without necessitating physical prompting, whereupon it is called ("Come") and appropriately rewarded. With practice, the dog will stop pulling altogether as the result this simple procedure combining directive leash training and positive reinforcement. However, until a high degree of reliability is obtained, the trainer must remain prepared to interrupt the dog's pulling efforts every time they occur. While walking on a slack leash, the dog is permitted to move freely about, sniff, lag behind, dart ahead (unless excessive), and otherwise enjoy itself; the only requirement is that it not pull against the leash—ever. As pulling behavior is controlled, a DRO schedule can be introduced such that the dog is conditionally reinforced regardless of what it is doing at the moment so long as it has not pulled for some brief period—a duration that is progressively lengthened as the dog's behavior improves. Orienting, sit, stay, and release modules can be practiced intermittently during slack-leash walking. In this case, the dog is prompted to orient by calling its name and, if necessary, smooching or squeaking to gather its attention, bridging the orienting response with a click, and then prompting the dog to sit with a hand and vocal signal. As soon as the dog begins to sit, the vocal bridge "Good" is delivered, followed by a food reward. The dog should remain in the sit position until it is released with an "OK" and hand clap. The quick-sit and the recall routines (orienting response, click, come to closed hand, "Good," food reward, and release) are both practiced during slack-leash walking.

FIG. 1.16. Orientation of a dog when in the controlled-walking position.

Controlled-leash Walking and Hip-hitch

Once a dog has learned to walk without excessive pulling, a hip-hitch and control lead can be used to help develop controlled-walking skills. In addition to not pulling, controlled walking requires that the dog stay on the left side, aligning its hip with the trainer's left leg (Figure 1.16). The hip-hitch consists of a carabiner hooked under a wide bite just behind a belt loop on the trainer's left side. A longish loop of leash is tied off 1 to 3 feet away from the bolt snap, a point determined by the size of the dog. The loop is hooked over the carabiner and attached to a halter, limited-slip collar, or prong collar, depending on need and circumstances. The hip-hitch provides a consistent source of response blocking and feedback limiting the forward movement of a dog beyond the limit set for controlled walking (Figure 1.17). Excessive pulling forward is countered by stepping abruptly back on the left leg and causing the dog to turn about. In addition, the standing end of the leash or control lead running from the knot to the handle can be manipulated in various ways to provide additional control and to transition to the heeling pattern. Only experienced trainers should use a hip-hitch on large and powerful breeds with a history of

FIG. 1.17. Hip-hitch. The position of the hitch-loop knot determines the amount of action that the control lead can produce. When the loop is tied off near the carabiner, little control-lead action is possible, whereas when the knot is set closer to the to the collar, more control-lead action is available.

hard pulling. In such cases, dogs should be both hip-hitched and under the secondary control of a halter via a closed-loop arrangement (see *Halter Collars*). The hip-hitch and halter system should only be cautiously used with potentially aggressive dogs and, then, only by knowledgeable and experienced trainers familiar with the risks and techniques needed to manage and control such dogs safely. In addition to control benefits, the hip-hitch provides a means to free the hands to perform other training actions, such as squeezing a squeaker or clicker, luring and flagging, targeting, petting, and handling treats and other rewards. Controlled walking is signaled by saying "Come on" or "Let's go," and excesses are discouraged with appropriate leash prompts paired with "Easy" or "Hurry up," as needed. The dog is released from heeling to controlled walking with the signal "OK" and released from controlled walking to slack-leash walking with "OK" and "Easy" as the dog reaches the limit set on its distance to range from the trainer. Abruptly stopping and stepping back on the left foot serves to counter the dog's pulling efforts. When hip-hitched, the action causes the dog to turn about in front of the trainer, whereupon it can be guided with the left hand to the trainer's side. Before continuing the walk, the dog is required to settle and wait for 3 to 5 seconds before continuing. The procedure is used as needed to discourage pulling and to encourage more appropriate walking behavior.

Halter Training

Halter collars can be very useful for certain dogs and owners, especially children and adults who are physically unable to control a dog otherwise. The muzzling-type halter systems are particularly useful for controlling aggressive dogs and limiting their nuisance barking when on leash. When a dog forcibly lunges into the leash while wearing one of these devices, it passively turns the dog's head around while clamping its muzzle shut if the dog attempts to back out of it. To obtain the most benefit from halter training, the trainer should make a conscientious effort to positively reinforce more appropriate slack-leash and controlled-walking behavior while the dog is restrained on the halter. DeGroot, the originator of the halter for dog training, views the halter as a tool that should be used to facilitate behavior modification with minimal discomfort to the dog. She fully acknowledges the potential abuse and misuse of such devices and stresses that the halter should not be employed as a passive means to control and restrain the dog, but used in the context of well-defined training objectives. The goal of halter control is to provide the trainer with a temporary window of opportunity for enhanced reward-based training efforts so that the dog can be gradually controlled without relying on halter restraint. The powerful head-turning and muzzle-clamping effect of

the halter should not be allowed to become a way of life for the dog. The ultimate goal of halter training is to eliminate the halter (DeGroot, personal communication, 2002).

In addition to halters that exert a clamping action, fixed-action halters can be used to promote improved walking behavior. The fixed-action halter system is a versatile and effective tool for controlling excessive pulling (see Figure 1.7). The nonclamping halter has the advantage of comfort with the delivery of directive force without pinning a dog's muzzle shut. Since the fixed-action halter does not produce a muzzling effect, it is not intended or suitable for use with aggressive dogs. The design of the fixed-action halter causes pressure to be properly distributed in accordance with a dog's forward or backward movement. When a dog pulls forward, the force is directed toward the muzzle, whereas, when the dog pulls back, the force is directed to the neck loop and the back of the dog's head. In contrast, pulling back on muzzling-type halters causes the muzzle loop to clamp down on a dog's muzzle rather than primarily directing the force to the neck loop, where it is most needed for comfortable control. The muzzle-clamping action of many halter designs appears to cause some dogs a great deal of distress when they are first introduced to them. Such dogs appear to accept fixed-action halters with less resistance or struggle, making them more acceptable to concerned owners, as well. In addition to the fixed-action halter, a halter/limited-slip collar is frequently used to train adult dogs. The nonclamping, halter/limited-slip system employs both head and neck control pressure so that collar pressures are more evenly and safely distributed around a dog's neck and muzzle (see Figure 1.3). When used as a halter, it produces a very pronounced effect with a minimum of leash pressure and, since torque is distributed to both the neck and the muzzle, it can be safely used to deliver directive leash prompts. When the muzzle loop is removed, the collar becomes a limited-slip collar with a tab. In situations requiring added control, the muzzle loop can be quickly placed over a dog's nose.

Perhaps the most important consideration in halter training is proper introduction. Halters should be introduced slowly with lots of encouragement and positive reinforcement. Efforts by a dog to struggle against or remove the collar should be immediately and firmly discouraged, however. A dog should not be allowed to flail about or scrape at the collar. Such behavior should be countered with an upward leash prompt every time it occurs, followed by positive reinforcement when it stops, until the dog accepts the collar. The scent of orange oil on the hands appears to help some dogs through the transition. A few drops rubbed on the hands and placed

FIG. 1.18. Starting exercise.

directly in front of a dog's nose appears to produce a rapid reduction of distress. The fixed-action collar should be carefully fitted on a dog so that the muzzle loop is loose enough to allow the dog's mouth to open fully to pant and to take a ball, but not so loose that it falls off. The neck loop should be adjusted to fit closely around the back of the dog's head, with minimal slack or ability to slip over the dog's head. In the case of highly active dogs or dogs with thick necks, the fixed-action halter can be hitched to a nylon-slip or chain-slip collar for added security.

BASIC EXERCISES

Starting Exercise

In addition to coming and sitting in front of the trainer (sit-front), a dog should learn to go on signal to the trainer's left side and sit. The movement is prompted by tapping the left thigh and then taking the leash midway down with the left hand, whereupon one step is taken back on the left foot and the dog is gently guided around by the left hand (Figure 1.18). Initially, the trainer may need to take several steps backward or execute a heel-to-toe skipping movement to get the dog moving in the right direction. As the dog's head reaches a position just behind the trainer's left side, the trainer takes one or two steps forward, causing the dog to turn about and align squarely at the left side before it is prompted to sit. When the action is completed, appropriate social and appetitive rewards are delivered. After a moment, the dog is released with an "OK" and clap, and the trial is repeated. Once the exercise is mastered, the vocal signal "Heel" is paired with the hand and body signals used to prompt the behavior.

The starting exercise can be introduced by a shaping or luring procedure. Effective shaping depends on breaking the behavior down into simple steps. Initially, for example, any orientation or movement toward the trainer's left side is bridged and reinforced, especially movement occurring as the trainer steps back on the left foot. Next, the dog is required to follow the target hand a short distance toward the left before being reinforced. Finally, the dog is made to follow the hand around into the starting position and prompted to sit. Each step should be fully mastered before moving onto the next. A birdie lure can be effectively used to draw the dog around to the starting position (see *Targeting and Prompting*). In some cases, a resistant dog can be lured into position with a ball or a biscuit. Once the dog is moving into the starting position and sitting without hesitation, the lure is faded and replaced with the appropriate voice and hand signals. Performance reliability is enhanced with directive leash prompts, as necessary to cause the dog to move in the direction of the trainer's left side and to sit. The level of force used is determined by the dog's temperament and needs to achieve reliable compliance. Compliance to the sit command can be enhanced by pulling up on the leash while squeezing, at first gently and than progressively more firmly, across the hips just in front of the hip bones. The dog's rump should not be pushed down or slapped to increase compliance.

The dog should also learn to leave the starting position and to move forward, turn, and sit squarely in front of the trainer. The dog is guided into the sit-front position by capturing its attention, saying "Front," and taking a half-step forward with the left foot. As the dog follows, it is lured with the right hand or guided around by leash to sit in front. In addition to the left-side starting exercise, the dog should learn to go to heel by moving to the right side and then continuing on behind the trainer to the starting position on the left side. This route is typically used when the dog is located somewhere toward the trainer's right side, whereas the left-side hooking movement is used when the dog is located directly in front or toward the left side. Stepping back on the right foot signals the dog to go to heel from the right side. As the dog crosses behind the trainer, the leash is transferred from the right hand to left hand, and the dog is prompted to sit with the right hand as it reaches the starting position at the trainer's left side. The starting exercise is mastered by daily practice under varying and progressively more distracting and difficult circumstances. Also, the dog should learn to hold the position for longer periods before being released. The exercise is of tremendous

value for controlling dogs at times when increased close control is needed.

As the dog learns the starting exercise, an emphasis should be placed on requiring that it remain quiet and focused on the trainer for progressively longer periods. Sustained reinforcement lasting up to 15 to 20 seconds can be useful in the beginning to help keep the dog's attention in focus. Likewise, the trainer should take a moment to formally dress the leash, breathe, and concentrate on the dog and the training objectives, thereby joining the dog in the same moment of heightened attentiveness and appreciation. In the Japanese tea ceremony, the phrase *izumai o tadasu,* literally meaning to straighten one's kimono or posture, is a ritual preparation occurring in advance of preparing and serving tea, signifying an appreciation and respect for the guest and attentiveness to the moment shared with the guest in the making and taking of tea. A similar significance should be nurtured with regard to the starting exercise. As the dog comes to the trainer's side and the leash is carefully dressed, the trainer should collect the moment with an attitude of affectionate respect and appreciation for the dog's compliance and cooperation in the process of attaining interactive harmony.

Lying Down from the Sit Position

With the dog sitting in the starting position, the trainer changes leash hands and shifts in place about one-eighth turn toward the dog. The left hand (now holding the leash) is placed on the dog's shoulder and the thumb is hooked over the collar as the trainer crouches down. At the same time, the right hand is extended just in front of the dog's nose and moved downward toward the ground. As the result of the introductory lessons previously described, many dogs will naturally follow the hand's movement and lie down without hesitation. As the dog lies down, the bridge "Good" is spoken in a high-pitched tone, followed by a treat and sustained petting and massage once the dog assumes the down position. As the trainer stands upright, the left foot is placed over the leash so that the dog cannot prematurely break the down position (Figure 1.19).

The trainer should avoid pressing down on the dog's shoulder, since this may cause the dog to resist and push upward against the pressure. Lying down can be shaped through successive steps (e.g., targeting on the hand, following the hand as it moves downward, following the hand down to the floor and, finally, following the hand and lying down). Each approximation is bridged and reinforced and repeated as necessary to obtain a fluent response. In some cases, a toy or biscuit can be used as a lure to facilitate the response. The lure is kept just beyond the dog's reach as it is lowered to the ground. As previously discussed, food lures often function as a bribe; that is, luring the dog with a biscuit risks reinforcing its initial unwillingness to lie

FIG. 1.19. Down exercise.

down. In a sense, the dog's refusal to lie down may be calculated to manipulate the owner into bribery. As the result of success in such efforts, the dog may quickly learn that hesitating when prompted to lie down causes the owner to offer a bribe—a pattern that the dog is only too willing to reinforce! Habitually giving the dog the biscuit after luring may lead it to hold out and refuse to perform the response unless the bribe is in hand. A useful technique for fading the lure is to close the hand as though it might contain the biscuit when giving the down signal. After the dog is rewarded, it is either released with an "OK" and clap or prompted to perform another exercise from the down position (e.g., down-stay). Once the dog is lying down rapidly and consistently in response to the hand signal, the vocal signal "Down" is paired with it. As the trainer stands up, the leash is stepped on to prevent the dog from getting up. Down is practiced in a variety of situations and contextual relations to other basic modules and routines (see Appendix B.1).

In the case of dogs that refuse to lie down despite conscientious reward-based shaping and luring efforts, the following procedure can be useful for improving compliance. The slack of the leash is dropped to the ground and stepped on with the left foot. Next, the working slack is pulled out of the leash as the left foot is angled up 3 or 4 inches, with the heel planted on the ground as a point of leverage. The down signal is given and the foot is lowered to the ground, placing pressure on the dog's neck and forcing it to lie down. If necessary, the force is increased by repeating the procedure, causing additional leash to be taken up and producing a ratcheting effect that gradually compels the dog to lie down. In some cases, squeezing across the neck muscle at the withers, gently at first and than more firmly as needed to prompt the down response, can further enhance compliance when combined with the ratcheting procedure. Forceful stamping on the leash should be avoided in favor of more controlled and measured techniques.

Sitting from the Down and Stand Positions

The dog is prompted to sit from the down position by first rocking or shuffling slightly forward on the right foot and then, as the dog begins to get up, stepping back on the left foot and, with an upward movement of the right hand, signaling the dog to sit. As the dog sits, the response is bridged and reinforced. Next, to prompt the dog to stand from the sit position, the trainer dresses the leash across the left knee and then takes one step forward into the leash with the left foot. The step forward prompts the dog into the stand position, and the response is bridged and reinforced. As the dog stands, the trainer gently restrains the dog with the left hand on the collar so that it does not move too far ahead. If the dog attempts to sit, an additional step is taken—a procedure that is repeated together with a slight downward pressure applied by the palm or fingertips of the left hand to the dog's shoulders. The slight downward pressure causes the dog to push back, thereby competing with its tendency to sit. Once steady, the dog is released with an "OK" or prompted to sit. The dog should be required to hold the stand-stay at the trainer's left side for progressively longer periods. Once the basic response is established, the vocal signal "Stand" is paired with the step forward. The reliability of stand response is gradually improved by the practice of routine variations (see Figure B.1C in Appendix B). As the dog's training progresses, sit responses occurring in association with recall and sit-front, starting and finish exercises, and heeling are often encouraged to occur automatically (see *Automatic Sit*), requiring that vocal and hand signals controlling the sit response be gradually faded. Consequently, the vocal and hand signals prompting the sit response are primarily practiced for enhanced reliability in the context of controlled and slack-leash walking, stand, and down training (see Figure B.1A–C in Appendix B).

Integrated Cycle of Basic Exercises

The basic obedience repertoire consisting of the stand, sit, down, sit from the down, and stand from sit modules is practiced as a chain of interconnected routines in order to enhance the fluency of each step and to establish a balanced and reliable pattern of performance. Not only should these routines be

performed in the normal forward and reverse orders, they should also be practiced in various unexpected ways as the dog's skill and proficiency improves (see Figure B.1D in Appendix B). All the basic exercises are integrated with the stay and heeling pattern. As the dog's training progresses, the reinforcement schedule is varied so that the dog might be required to offer a series (twofers and threefers), such as sit and stand (a twofer) or down, sit, and stand (a threefer) for the same reward. Although food is given intermittently, each successful effort should receive appropriate bridging and affectionate encouragement.

Stay Training

All basic exercises are performed with an implicit stay; that is, a dog should remain in the position until it is released ("OK") or prompted to perform another module or routine. It is particularly important not to allow a dog to break the position immediately after receiving affection or food rewards.

Stay from the Starting Position

The sit-stay exercise is practiced by calling the dog by name, saying "Stay," and stepping off on the right foot, whereupon the left hand is swung back to take up the leash, and the trainer turns to face the dog momentarily. As the trainer turns, the working end of the leash is dropped. The remaining standing slack is let out as the trainer steps back, with the right-hand flag (palm out and held at chest level) toward the dog. The handle of the open leash hangs from the right thumb as the trainer steps back a few steps. Once at the end of the leash, the leash handle is changed from the right thumb to the left thumb, with any excess leash slack taken up into a single fold in the left hand. Finally, the right hand is placed over the left hand at waist level. If the dog attempts to move out of position, the trainer prompts the dog back into position or returns it to the original position.

The trainer goes back to the dog by retracing previous steps or by circling behind it. If the trainer opts to go around the dog, the open leash is flipped onto the dog's right side as the trainer starts around the dog's left side. The leash is gathered and dressed as the trainer returns to the starting position at the dog's right side. At the conclusion of the exercise, the dog is either released with an "OK" and clap or reinforced and prompted to perform some another task; the dog is never permitted to break a stay without a signal (See Appendix A).

Most dogs rapidly learn to stay. However, some highly excitable ones may require vigilant handling, response blocking, and directive prompting to control. Frequent or sustained reinforcement can be a highly effective means to initially encourage excitable dogs to stay and focus on the trainer. Well-timed vocal or leash prompts can prevent dogs from breaking the position and provide an additional opportunity for reinforcement. If a dog breaks the position altogether, it is returned to the original spot and the exercise is repeated. An active-control line (ring or post) can be used to facilitate stay and recall training via response blocking and reward training. The down-stay and stand-stay are practiced in a similar way as the sit-stay. Directive procedures and blocking are minimized by gradually establishing stay routines in small well-mastered steps. Stay training consists of eight separate but interrelated criteria, each requiring explicit training:

Criterion 1 *Duration:* The dog is required to stay for progressively longer periods while the trainer stands nearby or just out in front. As the trainer's distance away from the dog increases, additional duration criteria are added in advance of every increment of distance. Reliability associated with duration is the most important foundation or anchor of stay training. The duration phase of stay is associated with training the dog to hold eye contact with the trainer for progressively longer periods. Once a standard expectancy (see *Prediction and Control Expectancies*) is established, variations with respect to the frequency of rewards and the duration of the stay period can be used to help strengthen the stay exercise. During the early stages, the dog is given frequent rewards while its stays, learning only to move out of position after it is release with an "OK" and hand clap. Since the stay exercise is mildly aversive for most dogs, providing a dog with varied and highly valued rewards can be helpful, as can the

surprise generated by periodically releasing the dog sooner than normal.

Criterion 2 *Differentiation:* Differentiation refers to the systematic association of different basic exercises with stay training, until they are all equally steady and reliable, both as discrete modules (e.g., sit, stand, and down) and routines (e.g., sit from the stand, down from the sit, sit from the down, and stand) and as dynamic exercises (e.g., the walking stand-stay).

Criterion 3 *Distance:* Once the dog is holding the sit-stay, down-stay, and stand-stay for 30 seconds or so, the trainer increases the distance criterion by gradual increments. In the context of increasing distance, further differentiation and organization of basic modules and routines are continued while introducing and practicing distance exercises (e.g., sit from the stand, down from the sit, sit from the down, and stand), performed in conjunction with the walking stand-stay exercise. Initially, the trainer prompts these exercise at a distance of a step or two away from the dog, then at the end of the leash and at the end of the long line, and finally with the dog off leash (see *Walking Stand-Stay and Distance Exercises*). Practicing the recall from the sit, down, and stand-stay should be added only after a high degree of control is established over the distance exercises. Calling the dog from the stay should be calculated to produce surprise, thereby strengthening the stay and giving enthusiasm to the recall. With each step of increasing distance and differentiation, additional training and proofing of criterion 1 should be carried out, especially with respect to the proofing of the down-stay. With the trainer at a full leash distance, the dog should be reliable in a down-stay for a minimum of 1 to 3 minutes, 3 to 5 minutes at a long-line distance, and 10 minutes or more when off leash. Recall from the stay is practiced in the context of developing an interruption signal that causes the dog to stop after starting to come, to wait, or immediately to drop before being called to front and finish.

Criterion 4 *Direction:* The dog should be left to stay with the trainer walking away in various directions, for example, stepping off to the side, stepping back, stepping toward the front, and sharp turns off to the left or right. When introducing directional variations, further differentiation and reliability of basic exercises is achieved by having the dog sit, stand, or lie down from various distances, directions, orientations (e.g., facing away from the dog), and locations relative to the dog.

Criterion 5 *Difficulty:* After the dog is staying reliably at a long-line distance, various elements of difficulty are added with the dog both close by and at various distances. Additional difficulty can be introduced by leaving the dog in unusual directions and ways and doing things out of the ordinary while the dog is in the stay. For example, the trainer can crouch down or sit on the ground, walk around the dog, run by the dog, fall down, roll over, rush toward the dog, or step slowly toward the dog. Additional difficulty can be added by leaving the dog's sight (e.g., hiding behind a tree or going around the corner of building).

Criterion 6 *Diversification:* Stay is integrated into everyday activities requiring that the dog stay or wait before getting what it wants, e.g., wait before being released to fetch a toy, before getting into a car, before being permitted to jump onto furniture, and before being let outdoors. With the transition to the long line, the dog should learn to halt and stay when chasing a throw-away object (e.g., a stick or other object of no critical significance to training objectives). After giving the dog a stay command, the object is thrown and, if the dog chases after, it the command "Stay" is shouted as the trainer tamps or stamps on the long line. The dog should wait in place until the trainer recalls it or releases it to retrieve the object. The halt-and-wait response is a critical preliminary to off-leash training (see *Using the Long Line*).

Criterion 7 *Diversions:* After the dog is solid under the foregoing circumstances, increasingly distractive situations are identified to proof the dog's ability to stay in the presence of attractive diversions (e.g., children playing, wildlife, other dogs, joggers, and bicyclists) while on leash and long line. The trainer can bounce a ball with the dog in a stay exercise, finally releasing the dog to chase or catch the ball. The quick-sit and instant-down are introduced in the context of prov-

ing the stay under highly distracting conditions.

Criterion 8 *Disruptions:* In addition to attractive diversions, the dog is also gradually exposed to potentially startling or aversive events with appropriate counterconditioning and graduated exposure, as needed to reduce its reactivity (e.g., traffic and loud noises) while practicing stay variations.

Stop, Stay, and Come

Occasionally, while walking on a slack leash, the dog is signaled to "Stay." If the dog hesitates and stops, the trainer should immediately bridge the behavior and approach the dog in a reassuring way, reward it, and release it with an "OK" and clap. If the dog fails to stop, the trainer anchors the leash on the waist with both hands and abruptly stops, thereby bringing the dog to a sudden halt. Besides learning to stop and wait while walking on a slack leash or long line, the dog should also learn to come when called and to sit-front. The trainer calls the dog by name, says "Come," and delivers a hand signal consisting of a sweeping action of the right hand moving across the chest. If the dog responds, the behavior is bridged with the clicker or vocal reward "Good," and the dog is directed to sit directly in front of the trainer. Taking a few steps backward as the dog approaches the trainer can help to facilitate straight sits. Finally, the dog is prompted to finish with the command "Heel," whereupon it should sit automatically. The dog is appropriately rewarded and released to repeat the exercise.

Quick-sit and Instant-down

The quick-sit involves training the dog to sit rapidly without hesitation, regardless of the dog's disposition or environmental circumstances. The quick-sit is an emergency exercise that signifies that the dog must stop whatever else it is doing and sit immediately and remain still until it is released. The quick-sit should involve a foundation of intensive reward-based training and directive enhancement, as needed to achieve a high degree of reliability under diverse and progressively distracting and difficult environmental conditions. The quick-sit is proofed in the context of intensive stay training. Like the quick-sit, the instant-down is a rapid and immediate emergency response. The dog is required simply to drop in place without hesitation. The module is introduced only after the dog is fluently lying down from a sit position. The first step involves training the dog to lie down from the stand. This task is facilitated by first training the dog to bow by targeting on a hand moving toward the ground. Once the dog is bowing on signal, instant-down while walking or heeling is much easier for it to perform. The task is prompted by turning slightly toward the dog and directing it with an excited tone of voice and downward hand signal to drop to the ground. If the dog fails to respond, the trainer lures or physically prompts the dog into the down position. As the dog complies, the behavior is bridged and reinforced, but the dog should continue to hold the down-stay until it is released. If the dog attempts to get up, the trainer stands on the leash with the left foot. At the conclusion of the exercise, the dog is either released, prompted to sit or stand, or walked out of the down position, depending on what is appropriate given the situation. This exercise is repeated several times in close succession until the dog learns to drop without hesitation. The instant-down can be facilitated with a ball lure and play following compliance.

Go-lie-down

Training dogs to go to a specific place and to lie down is a valuable exercise that all companion dogs should learn and regularly practice. The behavior consists of the dog leaving the proximity of the trainer or stopping some activity, moving to a designated spot, and lying down. This sequence of behaviors is first shaped using positive-reinforcement techniques. Training the dog to go lie down assumes a reliable and fluent down and instant-down response. Initially, the dog should be trained to go to a rug by using a shaping process. One way of accomplishing this is by using a clicker and shaping the routine via a series of approximations that train the dog to go to the rug, lie down, and stay there (Table 1.2). Once the dog is going rap-

idly to the rug or bed and lying down, the response is generalized to other places and contexts involving increasing distractions and difficulty (e.g., the presence of a guest or while the family is eating). Tossing a soft toy toward the spot where the dog is expected to lie down may help it to follow the pointing prompt. If necessary, the dog can be lured or ushered part of the way and then prompted to the spot by pointing and saying "Go." As the dog nears the spot, the command "Lie down" is given, and a treat is tossed to the dog as it lies down. Once the pattern is established, the whole command is given at once, "Go lie down," coupled with a pointing prompt toward the spot.

FIG. 1.20. Heeling position.

HEELING

In addition to slack-leash and controlled walking, dogs are trained to walk at heel. Formal heeling is a valuable lesson for every dog to master. When heeling, a dog remains close at the trainer's left side, without crowding or interfering with the trainer's movements. The leash is held in the right hand and dressed across the left knee. When the dog is heeling in the proper position, the working end of the leash intersects the trainer's line of movement at a 90° angle; that is, the dog is squared up at the trainer's side when heeling, neither moving past nor lagging behind this reference point (Figure 1.20). Heeling is an exacting activity, with a mere inch or two of deviation out of the position representing a flaw needful of adjustment. A close approximation is not enough, the dog is either heeling or not. There is a groove that is hard to describe but known to anyone who has trained a dog to

TABLE. 1.2. Shaping contingencies for the go-lie-down response

Step 1:	Turn away from the trainer
Step 2:	Turn away and orient in the direction of the rug
Step 3:	Move in the direction of the rug
Step 4:	Move with hand signal in close proximity to the rug
Step 5:	Move in close proximity to the rug and wait for reward
Step 6:	Pair hand signal with "Go," touch the rug, and wait for reward
Step 7:	Stand halfway on the rug and wait for reward
Step 8:	Stand fully on the rug and wait for reward
Step 9:	Hand and voice signal "Go lie down," go to the rug, wait, and down on hand signal before reward is delivered
Step 10:	Go to the rug, lie down on signal, and wait for reward
Step 11:	Go to the rug, lie down (signal faded), and wait for reward
Step 12:	Go to the rug, lie down, and wait to be released before receiving the reward
Step 13:	Go to the rug, lie down, and stay for a variable length of time before being released
Step 14:	Specify different locations to lie down by vocal and directional cuing

walk squared up at heel. Although the heeling position can be defined as a geometric relationship, in reality it is more a state of mind shared by the trainer and dog. Properly understood and performed heeling is a moving meditation during which the dog and trainer *join* in an attitude of cooperative purpose and heightened awareness of each other.

Again, the importance of preliminary training using a shaping procedure and play-based luring cannot be overemphasized. The trainer should always strive toward making training efforts as affectionate and rewarding for the dog as possible. Shaping a heeling pattern is introduced in a relatively distraction-free environment. The trainer attracts the dog's attention and encourages it to orient toward the left side, whereupon the approximation is bridged and the dog given the reward after it comes to the trainer's left side and sits. Sustained reinforcement helps to strengthen an impression that the left side is a desirable place to be. Using a licking stick slathered with peanut butter is one way to deliver sustained reinforcement while the dog is walking or sitting at the trainer's left side—a method that can be useful in the context of counterconditioning fears where sustained appetitive arousal is needed. With every occurrence in which the dog orients on the left side, a bridging signal is followed by a prompt to sit, "Good," and food reward. To make handling the various paraphernalia less cumbersome, the dog can be kept on a hip-hitch, thereby freeing the hands to signal, lure, and reward its behavior. Alternatively, the dog can be worked on a loose leash dragging on the ground or, in the case of more active dogs, a long line that is controlled by stamping actions. The usual pattern is to encourage the dog to orient and walk closely at the left side of the trainer before bridging and rewarding the behavior. By crouching down, turning about, running ahead, making various lip and squeaker sounds, and otherwise attracting and keeping the dog's attention, it will be more willing to play along and follow. Attracting the dog with a ball, luring it to the left side, and encouraging it to walk closely with right turns and right about-turns and changes of pace before allowing the dog to tug or fetch the ball can be a highly effective and fun way to introduce the concept.

Although play and reward-based training is a desirable way to introduce some of the basic elements, heeling as a formal activity is rarely fully attained without some element of directive training, as required to control the influence of distractions on a dog's wavering attention and impulse control. However, by carefully preparing the dog with preliminary play and reward-based training activities and making heeling a fun thing to do, the dog is certain to require far fewer and less forceful prompts than would be otherwise necessary to control its attention

Major Faults

At the beginning of every walk, dogs should always be given the liberty to walk at ease on a slack leash or long line, giving them a moment to relax and eliminate, if necessary. In the case of highly excitable dogs, ball play can be a useful way to dissipate excess energy. Once a dog is walking without pulling, it is called to the starting position at the trainer's left side and prompted to sit. The leash is dressed and, after a brief moment of affectionate praise and petting, the trainer gathers the dog's attention with its name and the command "Heel" and steps off on the left foot, slapping the left thigh, and smooching and clucking as needed to attract the dog's attention. If the dog forges out in front, the trainer drops the leash slack and turns away from the dog. As the turn is made, the left and right hands are drawn together and anchored near the left hip. The right hand is closed firmly around the leash handle, while the left hand is held open with thumb forming a crook over the leash. If the dog lurches to the side instead, the trainer turns sharply to the right. When applying directive prompts, the leash should be adjusted up or down on the thigh to keep it level with the line of the dog's back. Careful timing is crucial; if the slack of the leash is taken up too soon or too late, the effect is diminished or lost. The collective movement of the shoulders, hips, arms, and legs are coordinated to join up just as the dog gets to the end of the leash. As the dog turns and follows, the trainer should continue walking in the opposite direction for a few steps before resuming the original direc-

tion. As the dog follows along, its behavior is appropriately bridged and reinforced, with the trainer periodically stopping and prompting the dog to sit and rewarding it with affectionate praise, petting, and food.

Minor Faults

As dogs learn to stay back, changes of direction and leash prompts are used to refine the heeling pattern further. Now, instead of dropping the standing slack, the working slack is used to generate the appropriate directive prompt. A closer approximation to the proper heeling position is obtained by making left quarter-turns and about-turns into the dog. The left turn is made by taking up the working slack of the leash with the left hand, pivoting slightly on the left foot, and turning into the dog with the right leg. Short grab-and-release leash prompts delivered with the left hand can be used to improve slight out-of-position faults. Although such corrections are useful for polishing purposes, a broader brush is needed during the early stages of training, during which the left hand should refrain from holding the leash unless a directive prompt, left turn, or stop-sit prompt is being performed. To function efficiently, the change of behavior produced by the directive prompt should be bridged and reinforced with food and social rewards (praise, petting, and play).

Lateral lurching from the heeling position is corrected by turning to the right. This maneuver simultaneously exaggerates the fault (thereby making it more explicit and evident to the dog) and corrects it. Balking and lugging are corrected by dropping the standing slack and walking into the leash, combined with enticement actions (clucking, smooching, leg slaps) and vocal encouragement. Lunging is discouraged with brisk changes of pace and efforts to enhance the dog's performance motivationally with increased positive reinforcement and play. Stepping back abruptly into the leash with the right leg and then forward again on the right leg effectively discourages the dog from crossing behind the trainer. The various left and left-about turns, right and right-about turns, and changes of pace serve to zero the dog in on the heeling position. Throughout the training process, heeling should be continuously reinforced with vocal rewards and mechanical bridging, petting, play, and varied food treats.

Heeling Square

The quality and accuracy of the heeling pattern is gradually improved by employing various changes of pace (slow, normal, and fast) mixed with turns, directive prompts, bridging, and reinforcement. A heeling square can be used to refine and polish the heeling performance. The square can be indicated either with corner markers or by simply keeping the shape roughly in mind as one counts off steps from corner to corner. With the dog positioned on the outside of the square, the trainer says "Heel" and steps off on the left foot. After 6 to 10 steps, a sharp 90° right turn is made; this right turn is repeated three times, bringing the dog back to the starting point. As each turn is made, the trainer slaps his or her left thigh to draw the dog's attention, followed by appropriate encouragement and affectionate praise, as the turn is completed. Once back at the starting point, the trainer turns about so that the dog is now located on the inside of the square, and the dog prompted to sit and is reinforced. From this orientation, the dog is heeled around the square in the opposite direction by making a series of left 90° turns. Just before each left turn, the trainer picks up the working slack with the left hand, pivots slightly on the left foot, and steps in front of the dog with the right leg to complete the turn. As the square is completed in both directions, the trainer orients the dog toward the opposite corner of the square before prompting it to sit. The dog is walked at heel along the diagonal line between the corners and alternately prompted to make left and right about-turns. As each turn is completed, the trainer changes pace, saying "Easy" before slowing the pace or "Hurry" before speeding it up. After left and right about-turns with changes of pace, the dog is heeled around an imaginary circle traced within the square. The dog is first directed to heel around the square in a clockwise direction and then in a counterclockwise

direction. Walking clockwise requires the dog to walk slightly faster to keep up at the trainer's side, whereas walking counterclockwise requires the dog to slow down to stay properly aligned. At the conclusion of the foregoing variations, the dog is walked in a spiraling direction toward the center of the square, where it is left in long down-stay. After a variable period of 1 to 3 minutes, the trainer returns to the dog, releases it with an "OK" and clap, and engages it in ball play.

Automatic Sit

When walked at heel, a dog should sit whenever the trainer comes to a stop. In addition to sitting automatically while heeling, the dog should also learn to sit automatically after starting and finishing exercises and when called to sit front. The trainer's intention to stop is communicated to the dog by taking up the leash with the left hand and making a pulsing movement two or three steps before stopping. The slight movements of the leash announce the trainer's intent to stop, thereby preparing the dog to stop in unison with the trainer and to sit neatly at the left side. As the dog sits, the response is bridged and rewarded; if the dog the fails to sit, however, the trainer prompts the response with a hand signal, shadow, or knee bend and directive prompt. Crooked or awkward sitting is most easily adjusted or prevented by prompting the dog to adjust before it completes the action. If the dog begins to sit crookedly, it can be lured into the proper position or walked a step or two forward before being prompted to sit again. Alternatively, the dog can be prompted to perform the starting exercise before being prompted to sit straight. Attentive heeling in a proper alignment with the trainer prevents or solves many problems associated with crooked or awkward sits.

Interrupting the Automatic Sit

When walked at heel, a dog is obligated to sit automatically whenever the trainer stops. However, the trainer may prefer on some occasions that the dog not sit but stand still and wait instead. With such considerations in mind, an interruption signal is introduced that serves to set aside the obligation to sit and sets the occasion for the dog to stop and stand still instead. The automatic sit is interrupted with the vocal signal "Stand" while touching or gently pushing on the dog's shoulders or the back of its neck after coming to a stop. This stand prompt has been previously used to help the dog learn to stand from the sit or down position. If the dog begins to sit, the trainer repeats the command and takes an addition step forward on the left foot. The dog rapidly learns that a light touch on the shoulder or neck signifies that it should not sit, whereas the absence of such a signal by default indicates that it must sit automatically when the trainer stops.

Releasing the Dog from the Heeling Pattern

Proper heeling requires focused attention and the exertion of tremendous impulse control by a dog. Although it is beneficial and useful for a dog to learn how to heel, it is not beneficial to force a dog to heel all the time. Most dogs have so little opportunity to go on walks that it is only fair that such opportunities be made as cheerful and pleasant as possible for them, without the owner being towed around by an out-of-control dog. Normally, dogs should be walked on a controlled or slack leash 80% to 90% of the time and be brought to heel at times when more control is needed or as a means to discourage undesirable walking behavior. In accordance with the Premack principle (see *Premack Principle: The Relativity of Reinforcement* in Volume 1, Chapter 7), releasing a dog from the heeling position to controlled-leash or slack-leash walking can be used to reinforce good heeling habits. Consequently, it is best to release the dog while it is heeling nicely without pulling, sniffing, or looking around, whereas the dog is called back to heel when it becomes difficult to control while walking on a slack leash. Moving from walking the dog on a slack leash to a heeling pattern is mildly annoying and can serve to discourage undesirable walking behavior. After a period of heeling, the dog is again released and periodically reinforced for walking without pulling with appropriate bridges, treats, and opportunities to play. The

dog is released from heeling to controlled walking by saying "OK," changing leash hands, and flipping the slack leash onto the dog's back. The trainer releases the dog from controlled walking to slack-leash walking by saying "OK" and letting the slack slide out between the thumb and index fingers. When the appropriate amount of leash has been let out, the trainer says "Easy" and pinches the leash, thereby setting the distance given to the dog. The dog is brought to heel from slack-leash walking by transferring the leash from the left to the right hand, calling its name and "Heel," and delivering appropriate hand signals and leash prompts. With the left hand guiding the leash, the dog is prompted to turn about and come up sharply and squarely into the heeling position. Depending on specific needs, the dog is either allowed to sit automatically or directed to heel forward with the leash dressed neatly across the left knee.

WALKING STAND-STAY AND DISTANCE EXERCISES

The walking stand-stay is performed with the dog heeling at the trainer's left side. The exercise is initiated by saying, "Stay" and then sweeping the left hand back and taking up the leash, whereupon the trainer pivots slightly on the left foot before turning and stepping sprightly in front of the dog. As the trainer turns about, the leash slack is dropped, and the stay flag is presented to steady the dog as the trainer backs away from the dog. The exercise is practiced with the goal of training the dog to stop in midstride with the vocal and hand signals.

The walking stand-stay is introduced in the context of practicing distance exercises, including sit from stand, down from sit, stand from sit, down from stand, stand from down, and the recall routine. These various exercises are practiced at a half-leash and a full-leash distance away from the dog. As the behaviors are mastered, they are practiced with the dog on the long line and finally with it off leash. Sitting from the stand-stay is prompted by saying "Sit" and then sweeping the right hand upward to a point just below shoulder level. The down is prompted with the dog in the sit position by saying "Down," followed by a downward sweep of the right hand. Hand signals are delivered while taking a half-step on the right foot in the direction of the dog. The stand exercise is prompted from a distance by saying "Stand," together with a hand signal presented by shifting the right hand, palm down, first toward the dog and then bringing it back toward the hip. As the right hand is pulled back toward the hip, the trainer takes a half-step back on the right leg. As the dog moves into the stand position, the stay flag is presented with a step toward the dog to prevent it from moving out of position. If necessary, a stamping action is included to discourage forward movement by the dog when it is prompted to stand. Finally, the dog is recalled by calling its name and saying "Come" as the right hand is swept across the chest. The recall signal is also performed with a half-step back on the right foot. The forward and backward half-steps

FIG. 1.21. Active-control line with carabiner and webbing.

used to introduce distance exercises are gradually faded and then used only in situations requiring additional emphasis. When hand signals are presented, the fingers of the right hand should be held together, and the signal is performed neatly and consistently. Once the dog responds reliably to the vocal and hand signal combinations, the repertoire of basic modules and routines is practiced with vocal and hand signals presented alone. These various body and hand movements are also used in association with prompting delivered at a distance via the long line. In some cases, distant exercises are introduced with the dog on an active-control line (ring or post), thereby giving the trainer added control over the dog's forward movement (Figure 1.21).

The stand, sit, and down modules are practiced in various sequences and routines to promote balance and to prevent anticipatory responding. After the completion of each trial, the trainer should return to the dog to deliver rewards and initiate another trial or to release the dog. Distance exercises can be practiced in routines consisting of two or three modules at a time before returning to the dog. These basic exercises should be practiced under a variety of conditions of increasing distraction and difficulty. The recall sequence can be performed intermittently in the context of practicing distance exercises. However, repeatedly calling a dog from the stay after completing some exercise may cause the dog eventually to start breaking in anticipation of being called. Consequently, the dog should be called infrequently while organizing distance exercises and projects. The recall is practiced with the dog in sit-, stand-, and down-stay positions. Figure B.1A–D in Appendix B contains several sets of practice variations that are gradually introduced in accordance with the dog's training level. The variations are practiced in groups defined in terms of the dog's specific training needs. It is not necessary to practice all of the variations during the same session (practice may be limited to repetitions involving three to five variations per session), nor is it necessary to follow the particular order in which the practice modules and routines as are listed. These various exercises are practiced at progressive distances from the dog on a long line and off leash, as the dog's reliability permits.

Recall Training

No training project is more important than training the dog to come reliably when called. All companion dogs, but especially dogs exhibiting problem behaviors when off leash, should be trained to come and halt-stay to a high degree of proficiency and reliability. The habit of coming when called should be established early and practiced often. Puppies not trained to come when called before week 16 are typically much more difficult to train to come reliably as adults. Early training efforts should emphasize reward and play training, thorough environmental exposure and habituation, and varied daily practice activities. An unwillingness to come is most often the result of the combination of neglectful training and interaction that inadvertently trains the dog not to come when called. One of the most common mistakes leading to adult recall problems involves chasing a puppy that refuses to come or delivering punishment after catching or trapping a puppy on the run. Such interaction invariably promotes expectancies antagonistic to the development of a reliable recall. Another source of conflict and tension involves calling the dog from highly rewarding activities to less rewarding outcomes.

For instance, a dog that is kept indoors in a crate for the majority of the day often finds opportunities to go outside very exciting and enjoyable. Calling the dog back inside before it is ready demands that it give up a highly rewarding circumstance in exchange for a much less rewarding one. In this case, it would be more constructive to have the dog stay at the door and then to call it to come outside. After the dog has gotten its fill of the outdoors, its desire to come back inside will naturally improve, especially if strong incentives to do so are presented at such times. When the dog must be called from a highly rewarding situation to a less rewarding one, two methods are usually recommended: (1) The trainer goes to the dog and secures it without calling it. (2) If the dog must be

called, a 45-second period of diversionary activity and reward is provided (e.g., affection, treats, and ball play), thereby producing a buffer between the act of coming and a potential loss of reward.

Along these lines of inadvertent punishment, a common mistake is to call a dog to its crate. Crate restraint is far from pleasurable for most dogs and puppies (see *Dangers of Excessive Crate Confinement* in Chapter 2). The overall effect of calling a dog to crate confinement is to arrange a long exclusionary TO with restraint to occur when the dog comes, hardly an incentive to come when called in the future. In addition to being intrinsically aversive to the dog, the timing of crate confinement often signifies that the owner is about to leave the house, further increasing aversive associations with coming. Habitually calling a dog in order to confine it may result in its learning behaviors that are actively antagonistic to coming when called at other times, including the development of chase-and-evade contests when outdoors. Such activities are exciting, fun, and rewarding for dogs, serving to further reward the dog for not coming when called. Lastly, a poorly informed or impatient owner might fall into the foot-shooting habit of calling the dog to the site of a house-soiling or chewing incident in order to deliver a belated dose of punishment. Not only is such treatment ineffectual for producing the intended effect, it will strongly decrease the dog's future willingness to come when called, as well as adversely affect its trust in the owner.

Behavior shaped through positive reinforcement alone is reliable only to the extent that the dog is willing to work for the rewards offered by the trainer. In the case of food and petting, this readiness fluctuates widely depending on the dog's motivational state. Another important factor affecting the reliability of behavior shaped through positive reinforcement is the influence of extraneous contingencies of reinforcement (see *Distractions: Competing Sources of Reward*). For instance, a dog might find chasing a squirrel into the street much more intrinsically rewarding and immediately gratifying than anything the owner has to entice it to stay or to come. In this example, the opportunity to chase a squirrel may be more exciting and reinforcing than rewards controlled by the trainer (e.g., petting, food, and play). The learning theorist E. R. Guthrie (1938/1962) has nicely summarized some of the more important elements and pitfalls of recall training:

> A careful trainer follows the instructions to be found in an army manual: Never give a command that you do not expect to be obeyed. The reason for this is, of course, that a command that is followed by disobedience becomes an associative cue for the disobedient action. To train a dog to come when his name is called, the dog must first be induced to come. This can be done in various ways, and it is in his knowledge of these ways that the man who knows dogs shows his superiority. But whether he shows the dog food, or pulls the dog toward him with a check line, or starts away and trusts the dog to follow, it is the repetition of the name as the dog starts to approach that establishes the name as a cue for approach … To undo this training all that need be done is for the trainer to do as many owners do, call the dog's name while he is preoccupied with something else, or just as the dog starts off to chase a car, or in any circumstances in which the dog could not be expected to obey promptly. The name then becomes a cue for this particular form of disobedience and loses all its drawing power. (41)

Guthrie's observations are reminiscent of Thoreau's pithy journal comment: "When a dog runs at you, whistle for him." As a general rule, a trainer should never call a dog unless confident that the dog will comply or, if it fails to respond as expected, the trainer has adequate means at his or her disposal to ensure compliance. Calling the dog when one is uncertain of its compliance flirts with introducing a highly undesirable lesson, training the dog that it can sometimes escape the obligation to come when called, especially when under the influence of a highly motivational state. Ultimately, such training may teach the dog that the vocal signal "Come" signals an exciting opportunity for it to safely run away. Also, the trainer should avoid misusing the dog's name as a recall signal or reprimand. In obedience training, the dog's name should be used only to capture and control its attention—not as an alternative recall signal (Table 1.3).

TABLE. 1.3. Common activities that are counterproductive for reliable recall habits

Avoid chasing or cornering a dog that refuses to come. No advantage is derived from this effort, except perhaps in an emergency situation where no other alternative is available.
Never punish a dog that finally comes after at first hesitating or refusing to come when called.
Avoid calling a dog unless it is virtually certain that the dog will comply or that appropriate means are available to enforce the command should the dog fail to comply.
Avoid bribing or threatening. Whereas bribes reinforce the undesirable behaviors that prompt the bribes in the first place, threats are doubly inappropriate: they remove any positive incentive for the dog to come while at the same time revealing that the owner is unable to deliver on threats, so long as the dog remains at a distance.
Avoid repeating commands: repeating commands tends to associate the signal with behavior incompatible with coming when called. When running off, a dog is typically running toward something that is more rewarding at the moment than the owner. Calling a dog to come at such times may only serve to train the dog to run away on cue.
Whenever possible, avoid calling a dog from a highly rewarding activity to a less rewarding one.

One of the most challenging problems faced during off-leash training is training dogs to desist from running off after moving distractions, such as cars, bicyclists, runners, wildlife, or other dogs (see *Distractions: Extraneous Sources of Reward*). In addition to inhibitory training, proofing a dog while around such sources of stimulation is achieved through graduated exposure and counterconditioning—objectives that are facilitated by making use of a long line (see *Leash and Long Line*). The 30- to 50-foot long lines help to approximate off-leash conditions without totally relinquishing control over the dog. The dog should be given a certain fixed *search limit* that it must learn to avoid exceeding by turning back or by waiting for the trainer to approach from behind. The behavior of following, moving out, turning, and coming back (the search chain) is an innate tendency in most dogs. However, dogs not exposed to off-leash walks early in life may not show search-chain behavior, possibly because some window of opportunity or sensitive period for its expression passed in the absence of appropriate allelomimetic stimulation. In any case, as the dog reaches the limit of its range, the trainer should call its name (perhaps whistling or clapping if necessary to draw the dog's attention). Just as the dog turns, the trainer clicks and calls the dog by saying "Come" (see *Introductory Lessons*). At this point, running backward, crouching, or clapping may help to increase the dog's willingness to come. If the dog comes, it is rewarded with a variable food reward delivered from a closed hand, affectionately praised, and released immediately with an enthusiastic "OK" and hand clap. On the occasion of some successful trials, the trainer can toss the dog a ball, play tug, prompt it to jump up, or engage it in playful roughhousing. In the case of dogs that enjoy ball play, the ball can be thrown to the dog at different points in the performance of the recall sequence (as soon as the dog steps toward the trainer, after taking five steps, and so forth). The ball can also be thrown immediately after the dog alerts to its name or as it is released from a halt-stay at a distance. If the dog fails to come, it is prompted to "Stay!" whereupon the long line is stamped on to stop the dog from advancing farther. During the walk, a ball or stick is occasionally thrown for the dog to retrieve. If the dog attempts to bolt away or refuses to return with the object, the long line is used to block the behavior and to condition a halt-stay response. Since coming is consistently followed by reward and release, dogs appear gradually to acquire an expectation that returning to the trainer not only helps to extend the time they get to walk freely, but is also associated with a significant amount of reward in the form of affection, food, and play.

Orienting is nine-tenths of the act of coming, and many dogs can be successfully trained

to come by means of reward-based incentives and intensive conditioning of the orienting response. A significant population of dogs cannot be trained to a reliable off-leash criterion of control by reward-based means alone. Many of these dogs can be rapidly trained to come when in the safety of a backyard or when walked on a long line; however, this control does not evenly transfer to situations where the dog is off leash and exposed to competing sources of reward. Training can be additionally transferred by slowly and painstakingly fading the long line, but such efforts are ultimately confounded and slowly degraded by competing environmental rewards whose occurrence or nonoccurrence are not yet under the trainer's control. Although the dog can be taken to the very threshold of a reliable recall via expert and conscientious reward-based training efforts by integrating many sources of environmental reward, the process is ultimately dashed on the wall of a stubborn reality: reward-based behavioral control is only as good as the trainer's ability to control environmental rewards. The success of long-line training is based largely on its ability to block behavior seeking the gratification of competing sources of reward.

Although competing control modules and routines established by the rewards presented or withheld by the trainer can help, many

FIG. 1.22. Throw-rings produce a distinctive sound that is useful for establishing off-leash control.

sources of environmental reward occur independently of the trainer's direction and remain a constant threat to control efforts. Since most extraneous environmental contingencies remain as they were before training was commenced, the dog's behavior relative to those contingencies remains largely intact—a fact that the trainer and dog quickly discover when the long line is finally removed. Essentially, the training process has provided the trainer with a valuable foundation of enhanced control with which to manage the dog in the context of uncontrolled sources of environmental reward. Such management is not equivalent to a recall and a halt-stay response. The recall and halt-stay responses must function reliably to control potentially dangerous or harmful behavior operating in the presence of extraneous sources of reward (e.g., bolting out of doors, charging after bicycles, cars, and passersby, or chasing other animals), not simply manage it (see *Electrical Stimulation and Chasing Behavior* in Chapter 9). Traditionally, the transition from management to recall and halt-stay control was achieved by fading the long line while at the same time introducing a variety of remote inhibitory control devices. Throw rings can be useful for this purpose: they are relatively safe and have a distinctive sound that is not easily confused with other common sounds (Figure 1.22). Unfortunately, the use of throw rings and similar tools for proofing off-leash recall is something of an art, perhaps a dying one, that requires significant skill and experience to pull off successfully. In addition to the necessity of good timing skills, the trainer must be able to throw such things with a high degree of accuracy. Few average dog owners possess the necessary skills for using throw tools properly. In any case, with the advent of sophisticated remote-activated electronic collars, proofing recall and halt-stay with throw tools is rapidly becoming an obsolete practice (see *Recall Enhancement* in Chapter 9). Electrical collars can significantly reduce many problems associated with off-leash control in a rapid and humane manner. To optimize the effectiveness of electronic training and reduce the possibility of adverse side effects, preliminary reward-based recall and halt-stay training should be thoroughly

carried out beforehand. Dogs that have undergone such preliminary training usually require very little electrical prompting to make the recall and halt-stay responses significantly more reliable. Finally, the goal of electronic training should be to produce an opportunity for additional reward-based training and safe exposure to the many quality-of-life-enhancing activities made possible by means of establishing off-leash control.

House Training, Destructive Behavior, and Appetitive Problems

PART 1: HOUSE TRAINING

Adult elimination problems represent a significant source of distress for both owners and dogs. Not surprisingly, incomplete house training is the leading cause given by dog owners for relinquishing their dogs to the uncertain fate of the animal shelter (Salman et al., 2000), underscoring the importance of preventing and resolving house-training problems. Elimination problems are the result of a variety of causes, each requiring specific training programs to ensure effective control or management (see *Common Elimination Problems* in Volume 2, Chapter 9). The leading cause of household elimination problems, however, is improper or incomplete house training (Voith and Borchelt, 1985; Yeon et al., 1999). The majority of household elimination problems can be prevented with appropriate and effective house-training efforts begun at an early age. In general, adult

dogs exhibiting improper, incomplete, or unlearned house-training habits are treated in much the same way as puppies, until they are back on track.

HOUSE-TRAINING BASICS

The two primary goals of house training are to prevent the occurrence of elimination in the house while at the same time encouraging puppies to eliminate outdoors. Prevention depends on confinement or careful supervision while the puppy is moving about in the house. The importance of confinement and close supervision cannot be overemphasized. Keeping a record of house-training activities provides a useful source of objective feedback concerning a puppy's progress. Tracking daily house-training progress is especially useful in situations where a number of family members share house-training responsibilities (Figure 2.1). The chart allows others to see at a glance whether the puppy or dog has been taken out recently. The center column is used to indicate the number of accidents that occurred during the day, showing precisely how well things are going or not.

Confinement and Supervision

Effective house training depends on a combination of constructive confinement, diligent supervision, scheduled feeding, and the provision of adequate opportunities to eliminate outdoors. Several methods of confinement are used, including a loose leash, a crate or crate-holding pen combination, and tie-out stations. Crate confinement is particularly useful for initiating preventative restraint; however, as is discussed later in this chapter, excessive crate confinement may inadvertently produce significant adverse side effects. Over reliance on crate confinement may also interfere with effective house training by preventing a puppy from learning to generalize its training to the whole house. To optimize such generalization, a puppy should be exposed to all parts of the house while under influence of varying types and degrees of restraint, depending on its abilities. An easy way to accomplish this daily exposure is to walk the puppy around the house on leash or by tethering at various locations (tie-out stations) in the house. Tie-out stations consist of a length of braided nylon rope with a head loop and slide for easy fitting and removal. The puppy can be tethered in various ways, such as tying it to a piece of heavy furniture, knotting and slipping the rope under a closed door, or tying it to an eyehook screwed into molding. Initially, the length of tether should be approximately the sum of the puppy's height at the withers plus the distance from its nose to the base of its tail. Care should be taken to make sure that the puppy cannot become entangled in the tether or wrapped around something. Also, the tie-out station should not be close to valuable carpeting, furniture, or woodwork, since a puppy may chew while restrained. A blanket and toys that cannot roll away should be given to the puppy whenever it is tethered. As the puppy's reliability improves, the length of the tether can be gradually increased and finally eliminated via a fading procedure.

Although excessive crate confinement and isolation is not constructive, neither is letting a puppy run around the house unsupervised before it is ready for such freedom. In addition to inhibiting elimination, tethering offers several benefits that recommend its use. Unlike crate confinement, tethering provides more opportunities for the puppy to have close contact with family members while restrained. In addition to preventing inappropriate elimination, such restraint limits the amount of trouble the puppy can get into, thereby maximizing positive attention and socialization while helping to minimize punitive interaction. In the case of overly active or competitive puppies, tethering permits children to escape from mouthing and jumping excesses by simply scooting back out of the puppy's reach. Tethering also helps to constrain undesirable chewing activity by limiting it to appropriate chew toys left within the puppy's reach. Since tethering is frustrating for puppies, objects provided at such a time may acquire a preferential association as chew toys at times of increased frustration and emotional tension—an effect that may help to reduce destructive chewing later on when the dog is given more freedom to move about in the house.

Most accidents can be prevented if puppies are kept under careful observation and proper supervision. The owner should be instructed to watch for telltale signs both in body language and facial expression that have occurred in the past just prior to eliminating. Various signs can be used to predict and prevent future accidents (e.g., movement toward areas

that have been soiled in the past, sniffing and circling, whining when restrained by crate or tether).

There are various times when puppies are most likely to eliminate:

After awaking
After bouts of play
After any form of excitement
After eating or drinking and again 20 to 30 minutes later
After a significant period without eliminating

With diligent house training, most puppies can learn to eliminate outdoors with very few accidents. If a puppy is having several accidents every day, it is probably not the puppy's ability that needs to be improved, but the owner's supervisory efforts that need modification. When the occasional accident does occur, the owner should be prepared to respond appropriately and immediately to minimize adverse learning effects (see *Classical and Instrumental Learning* in Volume 2, Chapter 9). Elimination habits are under the influence of both instrumental and classical conditioning (Skinner, 1968), requiring careful attention to ensure that the behavior is brought under the control of appropriate environmental stimuli and reinforcement contingencies. Since the act of elimination is intrinsically negatively reinforcing for a puppy, allowing the puppy to eliminate in the house without a countervailing aversive consequence is tantamount to rewarding it.

Inhibitory stimulation should be sufficient to disrupt urination momentarily, but not so strong as to cause the puppy to become fearful or run away. For most puppies, an abrupt vocal shout combined with a clap or stomp on the floor is adequate to get the impression across. However, some puppies may require a stronger treatment involving the toss of some light object (e.g., a fluttering magazine) to instill a lasting impression. Whatever method is selected, it is critical that the puppy be caught in the act and then immediately rushed outdoors to finish it. Having the puppy on leash facilitates this movement outdoors. As the puppy is directed through the doorway, the owner's voice and manner should shift to a cajoling and encouraging tone, thereby causing the puppy to relax and finish the act outside. To improve the likelihood that the puppy will finish the elimination outdoors, it is imperative to catch the puppy at the earliest sequence in the act, ideally during preparatory or intentional movements. Although disrupter-type stimulation is appropriate and useful, excessive punishment should be avoided. Punishment causing a puppy significant discomfort or fear could cause it to overly generalize the event, thereby not only inhibiting elimination indoors, but possibly reducing the puppy's willingness to eliminate outdoors in the owner's presence, as well. A surprisingly large number of dog owners still believe that rubbing a puppy's nose in its mess is a helpful house-training deterrent. In a study involving people that had relinquished their dogs to an animal shelter, nearly 32% of those responding (N = 1947) believed that it was helpful to rub a dog's nose in its mess, with an additional 11.4% indicating that they did not know whether it was beneficial or not (New et al., 2000). Finally, retroactive punishment should be eschewed as an abusive misuse of punishment.

Placement Preference and Cleanup

Although the odor of previously deposited urine may act as an elimination cue, the importance of scent is often exaggerated, overshadowing other, perhaps more important, environmental cues affecting placement preferences. Actually, odor is one of many environmental cues informing placement preferences; others include habitual context and location, substrate, and remoteness from other basic biological functions (e.g., eating and sleeping). A poorly supervised puppy may urinate dozens of times throughout the house before the problem is finally recognized and brought under control, leaving many soiled areas undiscovered and uncleaned. Despite the presence of numerous indoor scent cues, once trained to eliminate outdoors puppies are rarely attracted back to these previously used and scented areas, suggesting that factors other than smell may be of greater importance in the development of placement preferences. Scent cues appear to play a much more significant role in the control of adult elimi-

nation patterns and urine marking. Some practitioners recommend the use of black lights, moisture-detecting probes, and biological dyes to find hidden urine spots, noting that, unless such spots are discovered, house-training efforts will be frustrated. In addition, high-tech, enzyme-activated chemical odor eaters are used to attack these attractants soaked into carpeting, ostensibly perpetuating marking behavior in adult dogs (see *Household Urine-marking Problems* in Volume 2, Chapter 9).

Cleanup after accidents should be thorough to reduce unpleasant odors and potential damage to carpeting and flooring. Rather than rubbing the urine deeper into the carpet, the key to proper cleanup is to first dilute and extract the urine. The first step is to get as much urine out of carpeting as possible. Paper balls, which make excellent disposable sponges for soaking up urine spots, are made by firmly wading together several sheets of newspaper into several softball-sized balls. In addition, these newspaper balls should be covered with a few sheets of paper toweling to protect carpeting from the ink on newspaper. As soon as an accident occurs, these paper sponges are used to extract urine by stepping and rocking on them. To dilute and further remove urine, a quarter cup of warm water is poured into the spot and then similarly sponged up. Finally, a solution of warm water and baking soda is poured onto the soiled area. The solution (one-quarter teaspoon of baking soda to one-quarter cup of warm water) is left to soak into the carpet for a minute or two and then thoroughly sponged out and allowed to dry overnight. When dry, the carpet can be gently brushed and vacuumed, leaving it clean and free of odor. The common practice of using vinegar should be avoided. Vinegar is particularly hazardous in the case of fine rugs. When exposed to sunlight, the acid in vinegar may produce a photochemical reaction with sunlight, causing sensitive carpet dyes to fade or discolor.

After the spot is cleaned and dry, a tie-out station can be set up nearby and the puppy restrained there for 15 to 20 minutes during the same time of day that the accident occurred. The puppy can be fed, massaged, trained, and played with over the spot. Also, the owner can seed the area with biscuits and allow the puppy to discover and eat them over the spot. A scent (e.g., an orange) associated with the puppy's crate can also be applied to the area. The goal of such training is to establish a number of associations with the area that are incompatible with the urge to eliminate, thereby replacing the expectations and preparatory sequences leading to elimination with those leading to the acquisition of food, toys, relaxation, and so forth.

House-training Schedule

A critical aspect of successful house training is the scheduling of meals and elimination opportunities so that they occur on a regular basis. Whenever possible, the puppy should be permitted to sleep in a bedroom. Initially, it may be necessary to confine the puppy to a crate placed next to the bed or tethered to a tie-out station. Before the puppy is confined for the night, it should be taken outside two or three times to give sufficient opportunity to evacuate fully. Giving the puppy a 10- or 15-minute walk before bedtime is a good habit for the owner to establish and maintain into adulthood. In any case, the owner should be prepared for the possibility of an early wake up, especially for the first week or two of house training. Whining in the middle of the night often signifies that a puppy is distressed by a need to eliminate. It is important for the owner to respond, but at the same time to push forward the puppy's biological clock steadily so that the puppy gradually learns to make it through the night. Instead of immediately responding, the owner should wait for a brief period before taking the puppy outside. During the first week or two, the puppy is progressively required to wait for longer periods until it can make it through the night. As the puppy's reliability improves, demonstrated by consistently making it through the night for at least 2 or 3 weeks, it can be gradually given more freedom to move about in the bedroom.

In the morning, the puppy should be taken to the same general location and vocally prompted to eliminate, using a voice signal previously paired with the act of eliminating. As the training process progresses, the puppy

should be encouraged to eliminate in different locations near and away from home, thus preventing the behavior from becoming overly contextualized to particular substrates and locations. When the puppy finally performs, it is rewarded with vocal encouragement and praise. Food rewards are usually not given to reward eliminatory behavior directly, but may be presented following defecation, especially if a puppy is coprophagous. Although elimination is intrinsically reinforcing, it is useful to provide additional social-positive reinforcement to counteract the generalized effects of punishment used to discourage elimination indoors. If a puppy fails to eliminate outdoors, it should be taken back inside and tethered or crated and taken out again after 15 to 20 minutes.

The length of time spent outside should be carefully controlled, with each outing not to exceed 1 to 3 minutes. Most puppies usually eliminate within the first minute after going outside. Instead of spending long periods of unproductive time walking and waiting for a puppy to eliminate, time outdoors is more efficiently used by giving the puppy several brief opportunities rather than one or two long ones. In the morning, most young puppies require three or four closely spaced opportunities outdoors to evacuate bowel and bladder fully:

Immediately after waking
Immediately after eating
20 to 30 minutes after eating
Again in association with outdoor play

During the day, multiple outings should be scheduled around feeding times. Between feeding times, puppies should be kept under close supervision or confinement, thereby preventing elimination from occurring inside the house. The average maximum length of time that a puppy should be expected to hold between daytime outings is calculated by dividing its age in weeks by 3. For example, an average 12-week-old puppy should be expected to hold for a maximum of 4 hours, with some puppies showing more or less control of elimination functions. Although some puppies are able to hold for longer periods, it may be stressful or unhealthful for them to do so. Initially, to minimize accidents, puppies should be taken out on a frequent basis (e.g., every 45 to 60 minutes) to establish the desired habit, gradually lengthening the period between outings to approximate the average age-appropriate limit. In addition to scheduled brief outings, two or more daily walks should be scheduled together with play sessions and positive training activities. Although requiring a puppy to hold for excessively long periods between outings should be avoided, giving the puppy too many opportunities to go outside may prevent it from acquiring appropriate eliminatory inhibitions. The crucial goal is to train the puppy to hold in response to internal elimination signals. Puppies that are taken out too often may not acquire this aspect of house training, but instead learn to respond to such internal cues as signals to eliminate or defecate. Not only must puppies learn to defer elimination to appropriate times and place, they must also learn to cope with the mild discomfort of holding a filled bladder or bowel.

Along these lines, teaching puppies to give a signal to go outside is a common, but questionable, house-training practice. While appearing reasonable and useful at first glance, encouraging puppies to give such signals may conflict with the objective of training them to hold and eliminate in accordance with an arbitrary schedule. Again, effective bowel and bladder control require that puppies learn to endure some amount of discomfort—an aspect of house training that is not necessarily served by training puppies to perform a signal to get outdoors on demand. Furthermore, such need-to-go signals depend on the owner being present to respond—a state of affairs that can rarely be maintained on a consistent basis. An unfortunate outcome of such training is the development of common elimination problems later. Unable to get the owner's attention with the elimination-need signal, a dog may go to the door and after a moment just turn around and eliminate nearby or run off to another room before eliminating, thereby reflecting the pattern previously established in association with the need-to-go signal, viz., give signal and then eliminate. Finally, many puppies rapidly learn to extend and generalize the need-to-go signal into a need-to-whatever-whenever sig-

nal, prompting the owner to go outside for purposes other than the dog's elimination. Such puppies learn that barking or pawing at bells can get them outside for play and other activities having nothing to do with elimination.

To prevent problems, the prospective dog owner should plan to take a two-week vacation to coincide with the puppy's arrival in the home to get the house-training process on track and perform other training activities. The owner should also plan to come home at lunch to feed and exercise the puppy for several additional weeks, if possible. Alternatively, a dog walker might be hired to take the puppy outside during the day. These and many other practical issues should be carefully considered before getting a puppy.

Common House-training Problems

The vast majority of puppies learn to eliminate outdoors on schedule with little difficulty. Most common house-training problems are the result of the following:

Fear
Distraction
Weather or surface aversions
Inappropriate interactive punishment
Improper house training

Fearful puppies that refuse to eliminate outdoors and prefer instead to eliminate after going back inside should receive appropriate behavior therapy consisting of graduated habituation and counterconditioning efforts. Puppies exhibiting specific fears should be exercised in locations away from fear-eliciting stimuli and only gradually exposed to such stimulation in association with counterconditioning. Fearful puppies should be provided with supplementary activities that promote feelings of safety and relaxation when outdoors (e.g., play and reward-based training). Overly active and inquisitive puppies may be excessively distracted by the novelty and excitement of being outdoors and fail to eliminate in a timely manner while on walks. Such puppies should be consistently taken to a familiar spot where exploratory interests have been habituated and only permitted to explore after eliminating (Borchelt, 1984). Puppies that refuse to eliminate as the result of weather changes or surface aversions should be provided with a surfaced area that is acceptable to them or taken to spots that are protected from the weather. Puppies should be gradually exposed to varying surfaces and weather changes to improve their willingness to eliminate. Rather than constraining its options, a puppy should be allowed to choose it spots, thereby facilitating more rapid habituation and willingness to eliminate in a timely manner. Walking the puppy to a remote part of the yard or requiring that it eliminate within a small area should be avoided, especially in puppies showing signs of inhibition about eliminating outdoors. Occasionally, as the result of inappropriate interactive punishment, the puppy may become anxious about eliminating in the presence of the owner, regardless of location, preferring to hide when back inside. In such cases, the punitive interaction should be discontinued and the puppy allowed to range away to a safe distance when taken outdoors. In addition to vocal encouragement, such puppies should be given food rewards or play after eliminating outdoors. Puppies that fail to eliminate outdoors should be taken back inside after 3 minutes and kept under close supervision on leash for 15 to 20 minutes (or longer depending on age and need) before being taken out again. This pattern is repeated until the puppy finally eliminates.

Dogs that habitually eliminate in the crate pose a significant problem (see *Elimination in the Owner's Absence* in Volume 2, Chapter 9). In cases were the behavior occurs overnight or at other times when the owner is present, increased opportunities to go outdoors may help to get the dog back on track and encourage better control. Sometimes simply making the crate smaller by inserting a divider can be helpful. However, in some cases, dogs may have simply lost their capacity to hold, perhaps as the result of repeated exposure to crate confinement exceeding their ability to hold. As a result, instead of holding in response to bladder signals, such dogs may simply learn to let go and urinate, often responding to progressively earlier signals in the sequence in advance of any significant discomfort associ-

ated with the holding effort. In other cases, the puppy may simply not exhibit sufficient inhibitory control over urinary sphincters to hold for long. Training such dogs to hold in the crate may require the use of a urine-activated alarm, giving the dog immediate feedback whenever it eliminates in the crate. The alarm consists of a moisture detector (available at most hardware stores) attached to quarter-inch cooper adhesive tape applied to a plastic crate tray (Figure 2.2). Two lines of tape are laid in parallel to each other so that a spiral form is made covering most of the tray surface. The tray is covered with a thick, open-weave blanket or a pegboard, allowing urine to run through and make contact with the copper tape. Now whenever the dog urinates a circuit is completed causing the moisture detector to activate an alarm that has been fastened to the inside of a plastic cup and appropriately muffled to match the auditory sensitivity of the dog. This arrangement is only suitable for use when the owner is at home or at bedtime, providing the owner with a signal while at the same time helping to inhibit urination in midstream. Such devices do not automatically reset and need to be manually switched off and urine wiped off the copper strips, making them unsuitable for dogs that are left alone in their crates.

FIG. 2.2. Moisture-detector alarm.

Another frequent source of house-training problems is preliminary paper training. Depending on the procedure used, paper training often violates both of the central imperatives of house training by allowing puppies to eliminate at will while indoors, albeit on papers or thereabouts. Owners often mistakenly choose the paper-training option to make the process easier for puppies and more convenient for themselves. A common adult elimination problem stemming from paper training is the tendency of some dogs thus trained to refuse to eliminate while on walks or when released outdoors, but instead waiting until they get back inside to eliminate—papers or no papers. Frustrated owners of such dogs are often at a loss to understand the origin of the behavior until the logic behind it is explored. Such dogs are performing in a manner consistent with the training that they received during an impressionable period of development for such learning. Although paper training is justified in the case of owners living in high-rise apartments or ones having disabilities or health problems, otherwise paper training should be discouraged. Of course, the temporary use of papers to protect flooring may be necessary if a puppy is left in a holding pen during the day. But even such stopgaps can result in problems such as the one just described, especially if such methods are used in an excessive and habitual manner. If the owner elects to paper train a puppy, the process should be performed in the same way as training the puppy to eliminate outdoors. Access to the papers should be restricted and allowed only in accordance with an appropriate house-training schedule. In most cases, efforts should be made to train the puppy to also use the outdoors, just in case such behavior becomes necessary in the future. Whenever possible, the first elimination in the morning should be performed outdoors to facilitate this dual training. Far from being easier, paper training, when properly performed, requires just as much, if not more, dedication

to achieve reliable control over the placement of elimination.

PART 2: DESTRUCTIVE BEHAVIOR IN PUPPIES

A common reason for seeking canine behavioral advice is destructive behavior. All puppies and dogs engage in varying amounts of exploratory and manipulative behaviors that may become misdirected into destructive activities (Figure 2.3). The problem is not chewing or digging per se, but rather chewing and digging activity that is inappropriately directed toward valuable personal belongings or things that may be dangerous to the dog. The goal of counseling and behavioral training in such cases is sixfold: (1) increase the owner's understanding of why dogs chew and dig, (2) identify evoking situations and contributory causes (e.g., separation distress, attention seeking, and insufficient exercise), (3) stress the importance of supervision and confinement, (4) discuss appropriate outlets for chewing and digging activities (e.g., chew toys and digging area), (5) discuss and demonstrate various techniques for discouraging destructive activities, and (6) provide basic training.

Puppies possess a need for a significant amount of daily chewing. Chewing provides stimulation and exploratory outlets, psychological benefits, metabolic (e.g., it elicits insulin secretion) and digestive effects, and a variety of homeostatic functions. Under the influence of adverse emotional arousal (e.g., barrier frustration) and inadequate exercise and social stimulation, chewing and digging activities may become exaggerated and problematic. As in the case of many other behavior problems, prevention is the key to the successful control of destructive behavior. Keeping puppies under a watchful eye and guiding their oral activities into appropriate outlets help them to develop habits incompatible with destructiveness. Strategic crate and pen confinement, tie-out stations, and leashing puppies help to reduce the likelihood that they will chew on forbidden items. Young dogs require a significant amount of social stimulation and opportunities to play, explore, and manipulate the environment with their mouths and feet. Playing various toy-oriented games (e.g., fetch, tug, and hide-and-seek) with puppies helps establish a durable preference for the toys used during such activities. Finally, puppies benefit from daily training activities consisting of following exercises, coming when called, sitting, lying down, and staying. All of these exercises can be introduced at an early age. Such training helps to improve puppies' attention and impulse control abilities, as well as enhancing their responsiveness to vocal control and direction.

FIG. 2.3. Puppies at play (John Hayes, 19th century).

ASSESSING AND CONTROLLING DESTRUCTIVE BEHAVIOR

Excessive oral activity may indicate a medical problem requiring veterinary attention. In cases involving abnormal destructive behavior and pica, a veterinary examination should be performed to exclude possible physiological causes. A general history and daily activity profile should be explored with the owner, including

Amount and type of exercise
Amount and type of play activities
Length and place of confinement

In addition, the trainer should obtain specific information about the objects chewed, the time of day when chewing is most likely to occur, and the various efforts already

attempted to control the problem (e.g., restraint, punishment, repellents, and so forth).

Selecting Appropriate Chew Items

Once an oral attraction is established, it may persist into adulthood and become very difficult to control or suppress. Consequently, it is important to encourage puppies to adopt an acceptable chewing pattern at an early age while they are most impressionable and receptive to such learning (see *Development of Exploratory Behavior* in Volume 1, Chapter 2). In addition to directing oral activities toward acceptable items, it is important consistently to discourage chewing directed toward forbidden household items. In addition to not being easily generalized and confused with forbidden items, a chew toy should meet three basic criteria: (1) it must maintain the puppy's interest, (2) it must sustain active hard chewing without being easily destroyed or eaten, and (3) it should not evoke guarding behavior. Although a nylon bone may satisfy criteria 2 and 3, it is not likely to be among a puppy's first choices in terms of attractiveness. A nylon toy can be made more appealing by drilling several small holes into it that are filled with cheese or peanut butter. Rawhide chew toys, while much more taste appealing, may not last very long, and many puppies may become overly possessive over them. Rawhide chew toys are better if they are slightly oversized and rolled, rather than knotted at the end. Despite the dire warnings in the trade literature to the contrary, rawhide chew toys are relatively safe for most puppies, but such toys may be inappropriate for dogs and puppies that chew through them too quickly. Rawhide toys are particularly appropriate after meals as aids in keeping the puppies teeth clean and facilitating digestion. After 20 to 30 minutes, the toys can be taken up and allowed to dry out between meals. Hollow rubber toys can be made more attractive by smearing peanut butter inside of them. Such toys can be safely left with a puppy when it is left alone, perhaps helping to ease mild separation distress by occupying the puppy. In addition to hard chew toys, most puppies, especially those prone to more severe separation distress, appear to be comforted by soft-cloth toys (Pettijohn et al., 1977), especially those scented with the owner's body odor. James (1961) studied toy preferences in puppies (2 to 3 months of age), finding that puppies exhibit definite preference toward soft or cloth-type toys:

> Those which elicited the most play were objects which could be bitten, carried in the mouth, held with the feet and pulled, and which could be held in the mouth and shaken. In general, soft objects were more attractive than hard objects. The piece of cloth with which two animals could play together definitely elicited the most play in the present study. (277)

Many puppies prize knotted ropes and fleece-type toys; however, such toys should be given only to puppies that do not destroy or eat them. For teething puppies, rope toys can be dampened and frozen.

Besides chew toys, puppies should also have access to a variety of interactive toys that can be used to play tug-and-fetch games. Training puppies to play tug games provides a constructive outlet for competitive play, with little risk of producing aggression problems (see *Play and Leadership* in Chapter 6). Consequently, tug games should be highly structured, with a beginning and end under the control of the owner. At the conclusion of a bout of tug, the puppy should release the toy (e.g., a ball with an attached loop of webbing), whereupon it is thrown a short distance away and the puppy encouraged to fetch it in exchange for another bout of tug or treat. Playing tug-and-fetch games helps to promote a positive association with toys and can be used to introduce new toys. Another useful game for introducing new chew toys is hide-and-seek. To stimulate interest, the puppy is briefly teased with a toy, which is then hidden out of sight but easy for the puppy to find. The puppy is told "Find it" and encouraged to find the toy. After repeated trials of such training, the puppy may learn to look for the item when motivated to play or chew. Another effective way to increase or maintain interest in chew toys is achieved by rotating them daily. This practice involves taking the toys up at night and giving them back at vari-

ous times during the day as a reward for good behavior or during bouts of play. Giving a puppy access to only a few toys at a time, occasionally taking them up and providing others, is another way to enhance their appeal. Whatever toys are chosen are of little value unless they are available to the puppy at all times. Remember that something is always within a puppy's reach when chew toys are not—clothing, molding, corners of furniture, rugs, plaster walls, and electric wires.

Many owners inadvertently facilitate undesirable chewing habits by giving puppies poorly chosen toys. For example, an old shoe may be offered to a puppy as ersatz toy in place of other shoes lying around the house. The owner soon discovers, however, that instead of satisfying a puppy's desire for shoes, giving it a worn-out one may only further increase its interest in shoes, worn-out or otherwise. Another common mistake is to forcefully remove forbidden objects from a puppy's mouth or attempting to capture a puppy by running after it to retrieve something that it has picked up. Instead of forcing things out of a puppy's mouth, it should be prompted to release objects by offering it a food treat in exchange. If a puppy has darted off with something, it is far better to call the puppy and reward it for relinquishing the object rather than trying to chase it down.

Whereas interactive games can help to instill an enhanced interest in toys, as well as reinforce cooperative behavior, chase games in which a puppy runs off with the toy in an effort to evade capture by the owner may promote a number of undesirable side effects, including an unwillingness to come when called and increased risk of producing undesirable possessive behavior.

Redirecting and Discouraging Destructive Behavior

To integrate a puppy successfully into a home, the puppy must learn not to disturb or destroy personal belongings. Although orienting a puppy toward acceptable chew toys is helpful, such efforts may not fully train the puppy to stay away from forbidden items. Eventually, such personal items as shoes, socks, undergarments, books, and plants will attract a puppy's interest. Keeping such things out of a puppy's reach is helpful, but eventually things are forgotten and left within the puppy's reach. Practically speaking, it is important, therefore, that puppies be trained to discriminate between forbidden household items and safe chew toys. Although direct techniques may ultimately be necessary to establish a sufficiently strong and durable object-related inhibition, indirect demonstrations may be useful as a starting point. Remarkably, an action modeled by a rival for the trainer's attention can have a powerful organizing effect on an observing dog's subsequent behavior, closely resembling what one might expect to occur if the dog had been directly stimulated instead of merely observing the model/rival (M/R) responding to the trainer's instructions and actions. Given the apparent benefits of the procedure for affecting object-oriented behavior, the M/R procedure should be explored in advance of going on to direct inhibitory training methods (see *Model/Rival Method*). While the M/R procedure may not establish a lasting deterrence or redirection of chewing activity, such preliminary demonstrations may help to reorient the puppy and, perhaps, make subsequent direct training efforts more efficient and rapid.

A surprising amount of control over destructive activity can be established by employing a novel stimulus (e.g., squeaker) to avert attention from forbidden items and reorient the activity to a more acceptable chew item. Clicker training can be used to enhance the puppy's orienting response to the squeaker (see *Orienting Response* in Chapter 1). Many puppies can be discouraged by saying "Leave it" firmly or by clapping and, if necessary, applying a leash prompt sufficient to turn the puppy away from the object and to redirect it toward a more acceptable item. Playing a tug-and-fetch game with the object can further enhance the puppy's interest in it (Table 2.1). The dog's sensitivity to directional cuing (pointing and glancing) can be used to help orient it to acceptable items, as well as improve its avoidance of forbidden ones. In the case of puppies that show a persistent interest in forbidden items, more emphatic disrupter-type stimulation may be

TABLE. 2.1. Managing puppy destructive behavior

Until puppies are reliable with regard to chewing activities, they should not be permitted to move freely about the house without supervision.
Puppies should be provided with supervised exposure to the home environment and surroundings sufficient to promote habituation, familiarity, and relaxation.
Attractive chew objects should be made available to puppies at all times.
Daily play, exercise, and social attention appear to reduce tensions associated with destructive behavior.
Disrupter-type stimulation and remote deterrents may be necessary to train puppies to stay away from forbidden objects. In addition to carefully timed corrections and booby trapping, repellents are often useful for controlling destructive appetites and excesses.
Puppies should be provided with daily reward-based training activities.

necessary in combination with behavior-activated and remote deterents. Forbidden items, especially those that have been previously damaged, can be used as temptations to help discourage future chewing by means of booby trapping and other deterrent techniques using startle and olfactory avoidance conditioning.

A highly effective deterrent is the sound made by a shaker can (see *Miscellaneous Items* in Chapter 1). A seven-penny can is usually sufficient. To charge the shaker sound, the can is tossed near a puppy that is engaging in a destructive activity with an object that has been scented with a novel odor (e.g., citronella-eucalyptus mix). The can should land close enough to evoke a startle response sufficient to stop the behavior, but not so close that it overstimulates or strikes the puppy. Alternatively, the forbidden scented item can be situated under a drop can, suspended by a length of dental floss held by the trainer and arranged to drop near the item but not risk striking the puppy. The suspended can arrangement allows the trainer to more closely define the level of stimulation produced (see *Three-step Deterrence: Step 3*). The can should contain cotton balls scented with the same odor scenting the forbidden item (e.g., electrical wires). The goals are to establish a conditioned association with the odor and to sensitize the puppy further to the odor by presenting it together with the startling sound of the can. As a result, the conditioned odor can be used on other items as an olfactory deterrent, as well as potentiating the startle effect of the shaker can, perhaps making the mere shake of the can an effective deterrent. Sniffing objects scented with a previously conditioned odor appears to cause puppies to react more keenly to the sound of the shaker as well as potentiating other sources of startle (e.g., vocal deterrents) used to control such behavior. In the case of sensitive puppies, a scented plastic vitamin bottle with holes drilled into it can be used as a shaker or a small scented beanbag can be used instead. Another way to establish a mild deterrent effect with sensitive puppies is by spraying a lightly scented stream of water toward the object at the moment the puppy approaches it.

Once a conditioned association between the olfactory stimulus and startle is established, booby traps should be set up to transfer control from situations in which the owner is present to situations in which the owner is absent or distracted. Booby traps are particularly important in the case of persistent, unhealthy, or dangerous chewing habits. A reliable method for doing this involves the use of a pull can. Tying a piece of dental floss to the ring of a shaker can and attaching it to the forbidden item rigs the pull can to fall when a puppy grabs at the object. The rigged can is placed on the edge of a shelf so that it will fall and land near the puppy but not strike it. Careful placement and testing of the arrangement can help to prevent such things from happening. A small amount of a conditioned odor is put on the forbidden item with a cotton swab. Objects can also be scented with a piece of paraffin wax that has been

melted and mixed with the conditioned odor. The pull can is strongly scented so that it delivers an impressive olfactory message, echoing the subtle odor on the forbidden object and reinforcing its significance as a warning signal. The net effect is to enhance the deterrence value of the subtle odor cue placed on the object and to provide a means to generalize the effect to other items without necessitating that an aversive startle be applied in each case. Another mild remote startle device is the upside-down mousetrap. This is especially useful for discouraging chewing on paper and similar light items (e.g., socks). The scented forbidden item as attached to the back of the trap with tape, and laid on the floor. If arranged properly, there is no risk that the puppy will be hurt by the trap as it snaps shut, but the odor and sound of the trap makes a clear and lasting impression. In some persistent cases, a shaker can or mousetrap is arranged in combination with a motion-sensitive alarm, so that the alarm is activated before the pull can or mousetrap is triggered, thus magnifying the effect of the event as well as providing reliable feedback if the puppy returns to the scented object (see *Controlling Inappropriate Chewing Activities).*

Most puppies quickly learn to stay away from forbidden things when some variation of the aforementioned methods is used. Of course, puppies that engage in excessive or dangerous chewing activities should also be carefully managed with crate confinement and tethering to prevent the unwanted behavior. Severe physical punishment (slapping and spanking) for destructive chewing should be eschewed because it will do little to control the chewing problem, but may generate undesirable fear and avoidance behavior. Although commonly practiced in error, belated punishment serves no useful function in the control of destructive chewing. Deterence that does not immediately precede or contiguously overlap the unwanted chewing should be avoided. Brief gentle scolding, although technically questionable, may produce a reminder effect in dogs that have previously received inhibitory training; that is, showing the item to the puppy or dog and saying "Not yours" or "Leave it" may not be without some benefit. Even if the procedure does nothing, nevertheless, it appears to help owners by giving them a way to let off steam in a controlled and inconsequential way. Alternatively, a model/rival procedure might be suggested as a better option for responding to after-the-fact situations, offering an approach that is more likely to produce a training effect without risk of adverse side effects (see *Model/Rival Method*).

Note: Puppies vary with regard to their sensitivity to startle. Consequently, startle-producing stimulation should be carefully adjusted to levels appropriate to a puppy's temperament and age. Particular caution should be exercised with young puppies, especially those between 8 to 10 weeks of age. Such puppies may be particularly sensitive to the effects of fear conditioning (see *Learning and Trainability* in Volume 1, Chapter 2).

PART 3: DESTRUCTIVE BEHAVIOR IN ADULT DOGS

A variety of adult behavior problems are associated with excessive chewing and other destructive behaviors (e.g., digging and scratching). Storm-phobic dogs may exhibit pronounced destructive behavior directed toward walls and flooring in an apparent effort to hide or escape stimuli associated with a storm. Many juvenile and adult dogs show destructive chewing and scratching only when left alone, often as the result of separation-related arousal and distress. Other dogs may chew and engage in other destructive activities as the result of inadequate impulse control associated with hyperactivity and excessive excitability. Chewing and scratching directed toward window casements and doors may occur secondary to territorial aggression or predatory excitement evoked by animals coming into the dog's view. Destructive behavior associated with fears, separation distress, hyperactivity, compulsions, and aggression needs to be addressed in the context of treatment activities aimed at reducing the underlying causes by applying appropriate behavior therapy procedures. Dogs exhibiting unusual destructive behavior or pica may be suffering from an undiagnosed medical condition

(e.g., hypothyroidism) requiring veterinary examination to detect and treat properly. The owner should be encouraged to keep a record of destructive behavior, including information on the time of day, location, presence or absence of the owner, object damaged, and possible causes (Figure 2.4).

A common source of destructive behavior in adult dogs stems from ineffective training and management of play and exploratory behavior. Highly active and inquisitive puppies rapidly learn that owner attention can be consistently obtained by bothering forbidden objects. Grabbing socks, undergarments, chil-

dren's toys, and similar things serves to evoke a reliable and often entertaining activity. Some dogs appear to seek out and then daunt the owner deliberately with forbidden object, apparently with the goal of triggering a chase escapade through the house. Despite repeated scoldings, the behavior may continue unabated. If the owner ignores the dog, it may then chew the item. Dogs that have learned to grab and run off with forbidden objects may exhibit playful oppositional behaviors that require significant training and management to modify. In extreme cases, dogs appear to respond to the owner's disciplinary efforts as a provocative challenge to compete, causing them to become progressively resistant and difficult to control.

Such dogs often behave in precisely those ways that are most likely to yield the maximum amount of owner attention, often attention concentrated in a ritual of interactive punishment. Rather than discouraging the oppositional dog's game, however, the owner's ineffective punishment only seems to have an opposite effect. Driven by distorted attention-seeking incentives, oppositional dogs seem to thrive on negative attention as something desirable and rewarding. Oppositional dogs with destructive habits are often habituated to gradually escalating forms of punishment and, ultimately, may not be reached by the owner's most severe disciplinary efforts. In the context of punishing destructive behavior, low-intensity punitive events may be linked inadvertently with high-intensity reward outcomes (e.g., escaping owner control and running about with the forbidden object). As a result, the punishing event may become a signal entraining vicious-circle behavior (Brown et al., 1964), causing oppositional behavior and destructiveness to increase over time. As punitive efforts are applied again and again, a dog may learn to tolerate progressively more aversive events while at the same time acquiring a variety of escape and avoidance strategies to stay out of the owner's reach and to maximize the reward value of the activity. Instead of deterring the dog from engaging in future destructive behavior, the forbidden object becomes a discriminative stimulus setting the stage for a cat-and-mouse game. Playful opposition is often misunderstood as dominant behavior, but, more accurately, such dogs are most often simply incompetently and improperly trained.

Another common cause is excessive or inappropriate confinement or lack of daily stimulation. Dogs learn to become familiar with the environment by interacting with it. By sniffing, picking things up, scratching, digging, and running about, dogs gradually become comfortable with the environment via habituation. With familiarity and habituation come an increased sense of safety and a progressive ability to relax. Dogs that are excessively confined or restrained may not habituate to environmental stimulation normally, becoming highly active and inquisitive or reactive when allowed to move about freely to explore, sometimes resulting in significant damage [see *Environmental Adaptation (3 to 16 Weeks)* in Volume 1, Chapter 2]. Such dogs may get caught up in vicious cycle, such that excesses resulting from a failure to habituate cause the owner to confine and isolate the dog further, thereby making the problem worse. Dogs exhibiting excessive exploratory behavior in combination with destructiveness and pica need to be carefully supervised while gradually being given more room to move about, explore, become familiar, and habituate to the home environment. Borchelt (1984) has proposed that the space given to the puppy or dog to move about the home environment should be managed with a concern for basic behavioral and physiological priorities, adjusted in accordance with the dog's development and ability, while meeting the owner's needs to protect personal belongings, furniture, carpeting, and so forth from damage. Accordingly, space management serves three basic functions:

1. It provides for the biological and behavioral needs of a puppy.
2. It affords protection against damage to personal belongings, carpeting, and furniture.
3. It facilitates a puppy's behavioral adjustment to the human environment, appropriate to its stage of development and training.

In addition to generalizing house training to different parts of the house, space-management

strategies are used to systematically discourage destructive activities and introduce alternative chew items. The process of environmental adaptation is combined with integrated compliance training (ICT) and play. The cynopraxic concern for the establishment of interactive harmony converges with quality-of-life goals in the process of mediating the dog's adjustment to the home environment. The extent to which the dog is fully integrated into familial activities and free to move about the house is an important cynopraxic indicator of adaptive success.

BASIC TRAINING, EXERCISE, AND PLAY

Dogs exhibiting destructive habits in association with oppositional behavior usually benefit from basic training, which provides a structure of communication and rules that helps to resolve interactive conflicts and tension (see *Hyperactivity and Social Excesses* in Chapter 5). Many of the problems associated with this type of dog spontaneously improve as better attention and impulse control is established. As a dog learns to work for positive attention and rewards, a more stable and satisfying bond can be formed between the owner and dog, ultimately leading to greater cooperation and harmony. The goal of basic training is to provide oppositional dogs with a set of unambiguous social boundaries and expectations; above all, though, such training serves to systematically show them how to obtain what they want by means of cooperation. Opposition is drive energy not constructively channeled and put to work by training.

The development of refractory adjustment problems associated with destructive behavior often points to environmental deficiencies and problematic social dynamics. Whereas cooperative transactions serve to promote feelings of security (comfort and safety) and trust via reward, antagonistic and domineering transactions may produce significant conflict and a variety of emotionally stressful states or interactive tensions: anxiety, frustration, anger, fear, irritability, and so forth. A common source of persistent and harmful conflict and tension occurs in the context of ineffectual efforts to control undesirable or dangerous impulses. Dogs respond to punitive efforts differently depending on a variety of predisposing biological and experiential factors (e.g., prenatal and neonatal stress, early trauma, and deprivation), influences that may exert a lifelong effect by altering the dog's sensitivity and reactivity to aversive stimuli and conflict. Ineffectual, excessive, or abusive punitive efforts to control undesirable behavior may adversely influence emotional and behavioral systems most sensitive and vulnerable to reactive behavioral elaborations. An important aim of cynopraxic intervention is to systematically identify these points of interactive conflict and to mediate their resolution by means of counseling, appropriate training, behavior therapy, and environmental change.

Oppositional conflict develops in situations where the owner's control interests are contested by the dog's efforts to obtain reward. Particularly problematic interactive conflict of this kind develops in situations where behavioral limits are set by aversive means that are approximately equal to the motivational arousal driving the undesirable behavior, with the net result that the dog is equally averted and attracted to the situation. Over time, conflict and frustration may gradually escalate into defiance as the dog habituates to the owner's ineffectual punitive efforts, causing the owner to gradually increase the severity of the means used to constrain undesirable behavior, while the dog's desire for the forbidden reward object or activity continues unabatedly to grow. Such oppositional conflict and frustration may become ritualized, locking both the owner and the dog in a compulsive fixation from which neither is able to escape easily without outside help. Often the key to resolving such problems is to identify what the dog is trying to achieve and then providing it, or giving the dog something equivalent in value, on a contingent basis, thereby satisfying the dog's desire for reward and the owner's desire for control. The spell is broken as the owner learns to lead and show the dog how to gratify its needs, rather than just obstinately standing in the way.

Effective training for these dogs incorporates a balance of strategic confinement and integrated compliance training. Strategic con-

finement consists of crating, leashing, and tie-out stations located throughout the house. Keeping such dogs on leash in the house can be a highly effective means to prevent or discourage undesirable behavior. Basic exercises, such as sit, down, stay, coming when called, and walking on leash without pulling, should be trained to a high level of reliability and worked into daily activities until it becomes a way of life for owner and dog. Desirable activities and resources (e.g., attention, walks, food, play, toys, and affection) should be made available on a contingency basis, requiring that the dog perform some trained module or routine in exchange. While undergoing remedial training, the dog should be kept under constant supervision on leash or restrained in its crate or tethered to a tie-out station, gradually obtaining more freedom to move about unsupervised as warranted by improved household behavior. Simply training the dog to turn away from forbidden objects (squeak and click) and rewarding compliance by redirecting the appetitive activity into a more appropriate outlet can help to prevent problems, as well as provide a useful starting point for approaching already established habits.

In addition to daily obedience training, destructive dogs should receive daily periods of exercise and structured play activities. The dog's need for exercise varies according to the breed and temperament, with some individuals requiring much more daily exercise than others. A typical exercise program should include at least two 20- to 30-minute walks, once in the morning and again in the evening. For active dogs, an aerobic activity (e.g., ball play) should also be provided. Playful tug-and-fetch games with chew toys can help to focus a dog's interest on them.

Controlling Inappropriate Chewing Activities

The model/rival method can be incorporated in the context of helping. For a week, the dog should be carefully supervised and restrained to prevent access to inappropriate chew items. During this period, the dog should receive intensive attention and integrated compliance training. Emphasis is placed on training the dog to orient to the sound of a squeaker, a response that is rapidly bridged (click) and followed by a food reward delivered from the right with "Good." The dog should be trained to sit and stay reliably and to halt-stay and wait until it is prompted to come, to sit, or is released. The dog should also learn to walk on a leash without pulling, sit-stay, down and stay, make eye contact, and generally learn to cooperate. Chewing activity is restricted to a small assortment of attractive chew toys, provided during play and used as rewards for compliant behavior. The selected chew toys should be both attractive to the dog and resistant to sustained chewing. Appropriate toys should be given to the dog whenever it is tethered or otherwise confined. After this initial training and orientation toward appropriate chew toys, previously damaged items can be gradually reintroduced as temptations. For dogs prone to pick up and run off with forbidden items, the objects can be tied off to a piece of furniture with a piece of twine or attached to active-control line that allows the trainer to snatch it away from the dog. One object should be presented at a time in the context of redirecting the appetite to a new and acceptable chew object. The forbidden object is kept in full view of the dog as the trainer encourages the dog to tug and fetch the toy.

Model/Rival Method

A rival/model method of training may be useful in the context of modifying object-oriented behavior (see *Complex Social Behavior and Model/Rival Learning* in Chapter 10). The full value and significance of the M/R procedure for dog-training purposes remains to be determined; however, preliminary experiments by the author suggest that the technique may exert a potent and under appreciated organizing effect on a dog's behavior, especially with respect to modulating object-oriented behavior. For purposes of orienting the dog toward acceptable items and away from forbidden ones, the following M/R procedure may serve to enhance subsequent inhibitory training.

A trainer (T) and model/rival (M/R) sit on the floor with a puppy or dog that is tied

off on a tie-out or active-control line located a few feet away. The T and M/R stage instructive interactions around acceptable toys and forbidden objects. The T presents an acceptable toy to the M/R and says "Take it," which the M/R does, whereupon the T says "Good." The M/R puts a toy on the floor and picks it up again, and the T says "Good." Next, a scented forbidden item is held toward the M/R, saying "Leave it." In response to a vocal warning, the M/R should move slightly back, but then reach again for the object, at which point the M/R says "Leave it" in a more forceful tone of voice, causing the latter to flinch back once more. After a moment, the two objects are arranged on the floor at least 3 feet apart, and the dog is allowed to move toward them. If the dog goes to the acceptable item, it is rewarded with an excited "Good" and engaged in play. If the dog goes to the forbidden item instead, the T says "Leave it" and draws the dog back by the control line and picks up both objects. After a brief delay, the demonstration procedure is repeated, but now incorporating a seven-penny shaker can or modified carbon-dioxide pump. Again, the T offers the M/R the toy, saying "Take it" and "Good" as the M/R reaches and takes the toy. The same procedure as previously described is used when presenting the forbidden item, but now after the T says "Leave it," the can is shook once or a slight spritz of scented spray is delivered with a modified carbon-dioxide pump toward the object, and the M/R flinches back. Finally, both items are again placed on the floor and the is dog released. After choosing the toy, the T says "Good" and engages the dog in a brief period of play. If the dog goes to the forbidden item, the shaker is shook lightly or a brief spritz (not startling) from the pump is delivered, and the dog is pulled away from the object with the control line. Three trials of M/R training are performed per session.

Three-step Deterrence

In cases involving persistent appetites for forbidden objects and chewing in which other methods have failed or are inappropriate, the following method should help to ensure a lasting avoidance of forbidden items.

Step 1

With the dog on leash, the forbidden object is shown with the warning "Leave it," whereupon it is put on the floor. If the dog moves to take the forbidden item, a leash prompt is delivered with sufficient force to turn its head away from the item. In strongly motivated dogs, a fixed-action halter can be used to facilitate head control (see *Fixed-action Halter Collars* in Chapter 1). The entire procedure is repeated again until the dog shows an active avoidance toward the item. With every successful trial, the dog is praised, offered a treat, and encouraged to take an alternative item. The acceptable toy is presented to the dog, saying "Take it" in a playful tone. Prompting the dog to play tug-and-fetch with the object can be helpful at such times to enhance its interest in the item. Subsequently, the acceptable and ideally more attractive object is placed 1 or 2 feet from the forbidden object. The arrangement is intended to provide the dog with a choice between the acceptable item and the forbidden one. If the dog selects the acceptable item, the forbidden one is retrieved and removed. The dog should be petted while in possession of the acceptable chew item. This routine should be repeated in various locations throughout the house to generalize the effect.

Step 2

During step 2, leash control is gradually faded and a disrupter-type deterrent and conditioned odor are introduced to help further generalize the effect. With the leash dropped and dragging behind, the dog is taken to a room where a decoy and an acceptable chew toy had been previously left on the floor. If the dog goes for the forbidden item, the vocal signal "Leave it" is spoken in a clipped manner and a scented seven-penny shaker can is tossed next to the dog. If necessary, the leash is picked up and the dog is directed away from the object. The entire procedure is repeated, as needed, until the dog actively avoids the forbidden item and accepts the

alternative one. After a toss or two of the can, a single shake may be sufficient to produce the desired inhibition. In the case of dogs that are highly sensitive to auditory startle, the pennies can be put into a large plastic pill bottle. A scented cotton ball is put inside the bottle that has had several quarter-inch holes drilled into it.

Step 3

By the end of step 2, the dog should show an active avoidance toward the forbidden item while on leash and off, but the training process is not yet complete. A significant contextual cue controlling the avoidance so far established is the presence of the owner. Joseph Call and colleagues (Ainsworth, 2000; Call et al., 2003) at the Max Planck Institute in Munich have confirmed what applied dog behaviorists and trainers have long known about the influence of an owner's presence as a contextual cue, viz., dogs behave differently when they are under the scrutiny of a watchful eye. The researchers found that dogs can be readily trained to avoid food that has been placed on the floor, so long as the experimenter stays in the room and keeps an eye on them. Dogs tended to approach forbidden food in a more stealthy and roundabout way when they were closely watched, in contrast to the more direct approach used when the observer was absent, turned away from the dog, facing the dog with closed eyes, or distracted by some engrossing activity (e.g., playing a computer game). Dogs rapidly learn to control their behavior in accordance to contextual social cues, appearing to discriminate between contexts where the risk of interference is high (owner present) and where the risk of interference is low (owner absent or distracted). Consequently, the purpose of step 3 is to counteract this expectation of safety from interference when left alone by implementing various booby-trapping procedures. The most commonly used booby trap is the pull can, consisting of a scented seven- or 30-penny shaker can that is tied to the forbidden item by a length of dental floss and rigged to fall near the dog (Figure 2.5D). The can is placed on a shelf, top of a door, or other ledge in such a way that it lands close to the dog but without any risk of hitting it. Although the shaker should be strongly scented with a repellent odor, the item itself should only be lightly scented (e.g., stroked once or twice with a scented cotton swab). In some cases, additional stimulus dimension can be added and the startle effect magnified by placing a small paper cup on top of the pull can. The cup contains a small amount of water scented with a drop or two of the conditioned odor. In addition to protecting specific items, pull cans can also used to protect countertops and other areas, such as furniture. In this case, two or three cans are strung together along the length of the countertop with a single length of dental floss. Short lengths of dental floss can be attached to the line at various points that may then be fastened to temptations of various kinds (e.g., kitchen towels). When the dog jumps onto the counter or steals one of the booby-trapped items, the cans all come tumbling down with a convincing crash. The dog or puppy that grabs clothing hung over countertops can be strongly discouraged by hiding a shaker can inside of the item, so that when the item is disturb the shaker can tumbles down. Unrolling toilet paper is a common nuisance behavior that can be discouraged by placing a shaker can on the roll itself, often inhibiting the habit after a single startling crash of the can. Similarly, by taping the line of a pull can to the side of trash bins or directly fastening it to items inside the bin, a rapid and lasting inhibition about exploring such items can be established. In the case of persistent appetites for forbidden objects, regardless of the sort of pull-can arrangement used, the can should be rigged in combination with a motion- or movement-sensitive device that is activated in advance of the can falling down, so that the dog can avoid the startling stimulation by backing away in response to olfactory or acoustical warnings set up in close association with the protected object. The pull can is a one-time event, whereas the scent and motion-activated alarm is continuously available to deliver immediate feedback and warning to the dog.

Another important remote application of the shaker can is the drop can, which is different from the pull can in that it requires a trip line and trigger mechanism or must be directly

released by the trainer. A simple arrangement involving the drop can is used to discourage dogs from entering a forbidden area. The drop can is attached to a length of dental floss that is passed through an eyehook fastened to the wall or ceiling. An alternate method involves bending an opened paper clip to form an eye and taping it securing to the ceiling or doorjamb. Another eyehook is set up at the level of the dog's legs. The dental floss is passed through both the upper and lower eyehooks, stretched across the doorway, and hooked by a knotted loop to the trigger—usually a paper clip shaped to serve the purpose and taped to

FIG. 2.5. Various devices used to discourage destructive behavior: **(A)** motion, moisture, and vibration detectors, **(B)** remote electrical switch, **(C)** infrared alarms, **(D)** shaker can with materials to make a pull can, **(E)** modified compressed-air pump, and **(F)** various spring-loaded snapping devices.

the doorjamb or wall. The arrangement allows the suspended can to fall to the floor whenever the dog trips the scented dental floss. For exceptionally difficult dogs, an identical backup arrangement can be set up on the other side of the doorway. Applying a dilute repellent scent to the floor and doorjamb and using strongly scented drop cans helps to generalized the effect and provides a means to fade the trip-line and drop-can arrangement. Drop cans are occasionally used to discourage chewing on woodwork. Here, the line is passed through an eyehook, guided across the top of the door, passed through another eyehook and then pulled down and attached to a trigger device made by slipping the looped end of the dental floss under a splinter of damaged wood. If the dog returns to the area and attempts to chew, the can is released and crashes to the floor. Drop cans should be arranged and set up so that they do not fall directly on the dog.

Aversive Startle and the Control of Destructive Behavior

Effective aversive techniques should produce immediate and significant suppression, but not produce excessive fear or discomfort. Ideally, suppression should occur rapidly and after only a few exposures, often after a single event. Startling stimuli occurring in nature are often closely associated with potentially life-threatening events, with rapid escape and avoidance of such events serving to improve an animal's likelihood of survival. Organisms that required many exposures to a dangerous situation before learning to avoid it would be at a greater risk of injury or destruction than counterparts that rapidly learned to avoid danger as the result of one or a few exposures. Obviously, animals able to learn from a single exposure would posses a significant biological advantage over those not so prepared. Survival pressures appear to favor rapid escape and avoidance learning, especially with respect to exploratory behaviors that bring animals into contact with potentially harmful stimuli, requiring rapid appraisal and adjustments to escape or avoid them in the future. As a result, exploratory behavior appears to be highly sensitive to novelty and subtle changes that immediately precede startle-evoking stimulation. An important function of exploratory behavior is to detect potentially dangerous situations in advance of an injurious exposure. Since destructive behaviors often involve exploratory and appetitive incentives, they are highly responsive to aversive stimulation, with startle and behavioral disruption playing an important role in their modification and control.

Although aversive procedures often play a prominent role in the control of destructive behavior, such efforts should be used in combination with supportive reward-based training and efforts aimed at eliminating or reducing emotional and physiological causes contributing to destructive behavior. In addition, dogs need to be provided with adequate substitute outlets to satisfy their need for oral and somatic exploratory activities. Unless aversive control is combined with constructive positive training efforts, its deterrent effects are likely to be short-lived and may require many more repetitions to maintain. Another problematic aspect of aversive control is timing. Destructive behavior is often discovered long after the fact, tempting owners to apply punishment belatedly, but interactive punishment after the fact is unlikely to produce a beneficial effect and may only cause the dog to fear or mistrust the owner rather than helping to discourage the undesirable behavior (see *Separation Distress and Retroactive Punishment* in Volume 2, Chapter 4). Dogs appear, as Roberts (2002) has noted concerning animals in general, to be stuck in time and lack the ability to form episodic memories of long-past actions connected in a causal way to present consequences. Behavior-activated devices and booby traps provide the means to deliver startling consequences at the exact moment in which the unwanted behavior occurs, making such procedures highly efficient and efficacious.

Aversive procedures should only be used to achieve cynopraxic objectives not otherwise attainable by nonaversive means alone. Further, all training procedures that produce discomfort, startle, or loss should be applied in adherence to the LIMA principle and the dead-dog rule (see *Hydran-Protean Side Effects, the Dead-dog Rule, and the LIMA Principle* in Chapter 10).

MISCELLANEOUS DEVICES AND TECHNIQUES FOR DETERRING DESTRUCTIVE BEHAVIOR

Destructive habits and various nuisance behaviors occurring in an owner's absence often require special techniques and tools to resolve them. The transition from crate confinement to free or limited access to the house is facilitated by the use of behavior-activated devices strategically placed to discourage destructiveness, jumping on furniture and countertops, and keeping dogs out of certain areas without physical barriers. Such problems are often extremely frustrating since a dog may misbehave only when the owner is out of sight or out of the house. A common method for addressing this problem is to set up booby traps or to employ various behavior-activated electronic devices that have been designed to deliver a brief spray or electrical stimulus via a dog collar (see *Behavior-activated Electronic Training* in Chapter 9). Booby traps deliver an immediate disruptive event at the instant in which the unwanted behavior occurs, regardless of the owner's presence or absence.

Modified Mousetraps

Modified mousetraps can be used to discourage dogs from jumping on furniture, from damaging potted plants, or from entering forbidden outdoor areas. While some authorities recommend the use of mousetraps without modification (Hart and Hart, 1985), good results can be obtained with upside-down mousetraps and mousetraps that are modified by wrapping 6 to 8 inches of cotton gauze around the hammer and then taping it. Such an arrangement delivers a sufficiently startling impact without risk of injury or unnecessary discomfort to the dog. A few drops of a conditioned odor can be placed on the gauze, establishing an aversive conditioned association between the odor and the startle of the trap closing shut, thereby increasing the future value of the scent alone as an environmental warning and deterrence. The usefulness of the scent as a repellent is significantly improved by using this simple conditioning arrangement. For sensitive dogs or puppies, an upside-down mousetrap may produce a sufficient deterrence to keep them off furniture and away from forbidden areas. Scattering a few upside-down mousetraps on forbidden furniture can be a good deterrent for the sneaky lounger. Dogs with a penchant for exploring waste bins can be discouraged with a couple of upside-down traps placed under the trash. The interior of the waste bin can be scented with a repellent odor, so that the avoidance response is maintained even after the devices are removed. The upside-down mousetrap is especially useful to deter dogs keen on paper items. The forbidden item is lightly scented and fastened to the back of a mousetrap with a ring of tape and then laid on the floor or tabletop. An empty matchbook can be placed under the mousetrap to prevent the trigger from releasing the hammer too easily.

Caps and Snappers

Many devices using cap charges can be tailored to training purposes. The pull cap is a fireworks toy that is set off when two opposing strings are sharply pulled apart. The device is a loud and effective deterrent for dogs entering forbidden rooms or closets. One end is attached to the door and the other to the doorjamb. The cap should be placed up high near the top of the doorjamb to prevent flying debris from striking the dog. Perhaps the most versatile of this group of devices is the spring-loaded snapper. These devices are available in magic supply and novelty stores as exploding pens and coin rolls (Figure 2.5F). Once set, the least movement will set off the delicate mechanism exploding the plastic cap. Since the plastic cap flies off the cap snapper with some force, precautions should be taken to cover the device or insert it in a sandwich-size zip-lock bag. Also, the powder burn of the exploding cap can damage finished surfaces. It should be emphasized that cap devices should be used only as part of an overall plan of training and in most cases as a last resort. Caps and snappers are usually set up with scented objects or placed together with a motion-sensitive alarm that is rigged to go off before the cap.

Infrared, Moisture, and Motion Detectors

Various electronic gadgets can be highly effective high-tech alternatives to the previ-

ously described booby-trap devices (Landsberg, 1994). The most useful are those that are activated by infrared detection, motion and vibration, moisture, or radio signals triggering an electrical or spray event delivered by a dog collar. Infrared detectors contain a heat-sensitive sensor that passively responds to temperature changes caused by a dog walking nearby (Figure 2.5C). When the dog enters the field covered by the infrared detector, a high-frequency alarm is triggered and continues until the dog moves out of the field, whereupon it stops and resets. Such devices can be very useful for protecting both objects and areas, such as countertops and furniture. Other devices are designed to detect photoelectric disturbances caused by a dog's movement. The photoelectric detector works by producing a beam of light that is reflected back to a light sensor. When the beam of reflected light is broken, a chime sound or loud external alarm is triggered. These devices are commonly used in stores to monitor the entrance and egress of customers. An advantage of photoelectrical detectors is that they can be used to define a highly specific area or boundary. Both passive infrared and active photoelectric detectors can be used to deter a wide variety of destructive activities. Motion- and vibration-sensitive detectors are also available with a built-in alarm and a panic-button switch (Figure 2.5A). These devices are hung on doorknobs to detect intrusion. When the door is banged or opened, the alarm is triggered, continues for 20 seconds or so, and then resets. Motion detectors can be placed on furniture or attached to forbidden items by a length of dental floss in order to deter unwanted activities. Such devices are small enough to put inside a shoe, wrap in clothing, place in trash bins, and so forth. Because such devices produce a continuous loud noise for 20 seconds, they should be used only in situations where the dog is able to move into another room away from the alarm. Moisture detectors with built-in alarms can be modified in various ways to protect areas being licked or chewed by a dog. For example, wire leads with alligator clips can be attached to the moisture-sensitive probes and fastened to two strips of quarter-inch copper tape. The pieces of copper tape are applied to the chewed area leaving an eighth-inch gap between them. When the strips of mounted tape are shorted by lick and saliva, an alarm is triggered and continues until the dog backs away. Another simple moisture-activated device can be set up by hooking quarter-inch copper adhesive strips to a 9-volt battery. Again, an eighth-inch gap should separate the copper strips so that a short is formed between the positive and negative poles of the battery whenever the strip is contacted by the tongue and lips; the arrangement delivers a mild shock. In any case, a conditioned odor should be applied to areas and objects protected by electronic sensors and deterrents in order to help generalize the effect.

Compressed Air

The carbon-dioxide (CO_2) pump (available at bike shops or computer stores) is modified to make it a useful training tool. The modification consists of a small cotton wad that is inserted into the base of an inflation needle that is firmly screwed into the nozzle of the air pump. After screwing the inflator needle into the pump, the needle part is wiggled back and forth until it breaks off (Figure 2.5E). This simple modification serves two functions: it prevents an excessively forceful discharge of CO_2 air, and it permits the user to dispense an odor by means of highly controlled air pressure and directional flow, making it easier to direct scented or unscented air toward some nearby or distant location. The lever valve on the CO_2 pump allows the user to release a controlled amount of scented or unscented pressurized air, producing an inaudible mist, a faint spray, puff, hiss, spritz, or startling burst, depending on training needs. The CO_2 pump can be used in a variety of ways to interrupt behavior or to produce positive or negative conditioned effects. When used to limit destructive behavior, a scented spray is directed toward the forbidden item, thereby generating a significant startle while at the same blowing the object out of the dog's reach and scenting it with the conditioned odor. After two or three applications, the

odor itself acquires a significant inhibitory effect and can be directly applied to forbidden objects (Otto and Giardino, 2001). In addition, olfactory startle conditioning may potentiate a dog's response to other sources of startle (e.g., the pull can), making them significantly more effective when presented in conjunction with a previously startle-conditioned odor (Paschall and Davis, 2002) (Figure 2.6). Also, once dogs are sensitized to the sound of an air pump, simply making a hissing sound can produce a mild inhibitory effect. Although the aforementioned nozzle modification helps to improve the safety of the air pump, several safety precautions should be observed when using the

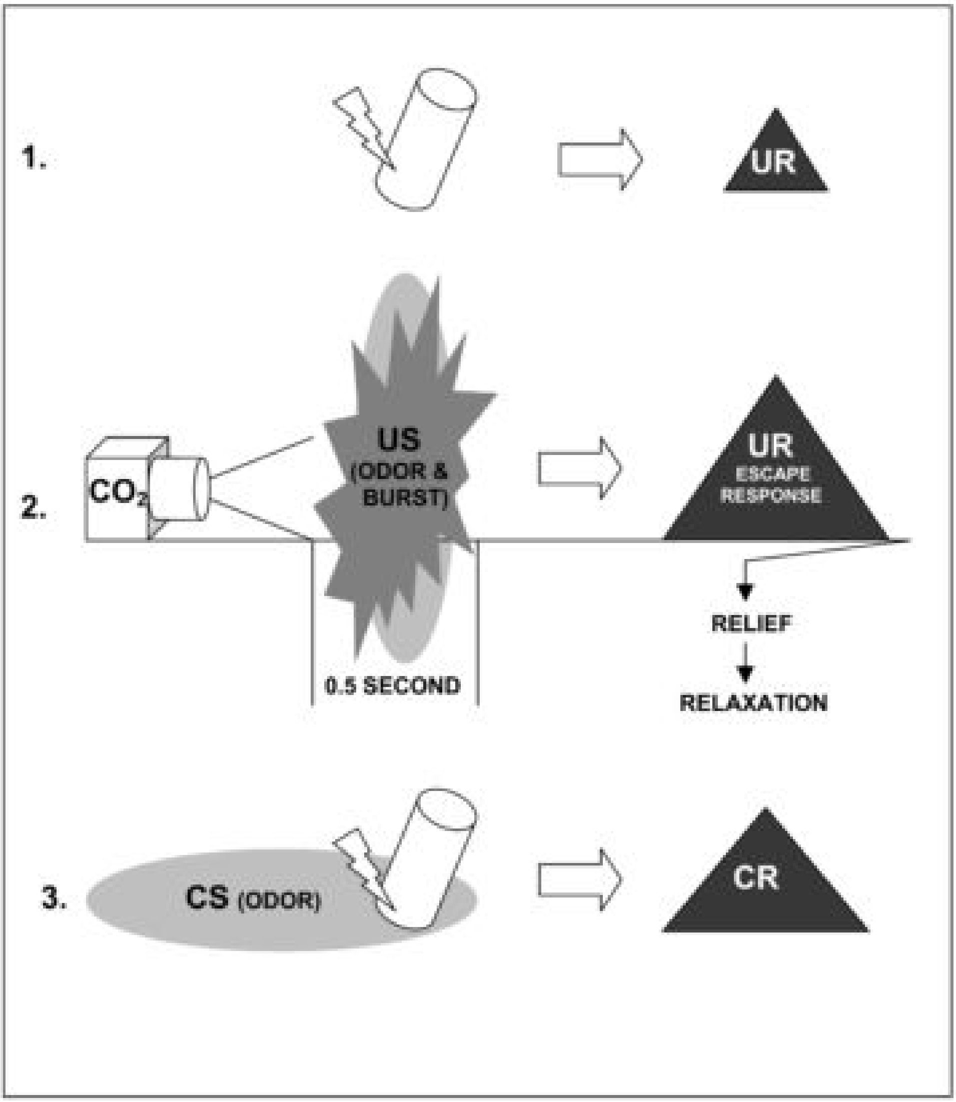

FIG. 2.6. Olfactory-mediated startle potentiation can play a valuable role in the control of destructive appetites and excesses. A previously conditioned odor applied to a forbidden item provides an avoidance cue as well as potentiating the effect of other startle events occurring in the presence of the odor. US, unconditioned stimulus; UR, unconditioned response; CS, conditioned stimulus; and CR, conditioned response.

device. The pump should never be pointed at the dog or sprayed toward the dog's face, near its ears and eyes, into its mouth, or directly against its skin. The discharge of compressed CO_2 may precipitate dry ice and cause burns if it is applied directly to the skin. Using the modified CO_2 pump safely and effectively requires some skill, and it should be kept out of the reach of children and family members not instructed on its proper use.

Repellents

Olfactory and gustatory repellents are commonly used to deter dogs from chewing and other destructive behaviors. In contrast to devices used to repel and deter dogs from engaging in destructive behaviors by stimulating auditory startle, chemical repellents serve a similar function by eliciting irritating sensations or disgust/nausea, as in the case of taste aversion (see *Taste Aversion* in Volume 1, Chapter 6). As previously discussed, conditioned odors produce a repellent event as the result of aversive conditioning in which the odor is paired with the occurrence of a startling event. A major drawback of repellents is that dogs may quickly learn to circumvent the strategy by avoiding treated objects but continue to chew objects that have not been treated with the repellent. Similarly, objects that have been scented with a conditioned odor may be avoided, but others not treated may inadvertently attract continued destructive interest. In the latter case, the absence of scent may actually help dogs to predict a degree of safety from aversive consequence. Repellents producing an acid, sour, or bitter taste do not appear to be very effective deterrents for the control of predatory behavior in wild canids (Mason et al., 2001) or scavenging garbage in dogs (Wolski et al., 1984).

Despite the aforementioned limitations, most dogs appear to respond to the deterrence produced by conditioned odors and repellents; however, when such substances are used in isolation from positive training activities, they probably do little good. Available commercial products offer varying degrees of effectiveness. With respect to repellents, odor-based substances do not appear to be very useful unless they are conditioned to evoke avoidance. The best repellents are those that directly irritate mucous membranes (Houpt et al., 1984), such as pepper derivatives (e.g., capsaicin). The most commonly used repellent substance is cayenne pepper in the form of hot sauce. Cayenne pepper can be also be applied as an alcohol extract/solution or paste. A mixture of cayenne pepper and alcohol consists of 1 tablespoon of cayenne pepper mixed into a quarter cup of alcohol. The mixture is thoroughly stirred and then let to sit for an hour or so, until the pepper granules sink to the bottom. The reddish alcohol solution that separates from the pepper is decanted and applied sparingly with a paintbrush or cotton swab to forbidden objects and areas. After application, the alcohol rapidly evaporates, leaving pepper resins behind on the treated surface. A paste of red pepper is made with water and small amounts of hair gel. The paste is typically slathered on wood objects (e.g., furniture and woodwork) that have been chewed in the past. Cayenne-pepper solution can stain or damage woodwork and fabrics, making the solution and paste inappropriate for some surfaces. Alum, an astringent, offers a mild alternative to cayenne pepper. Black pepper can be applied under the fringes of carpets or to other areas being chewed or scratched.

Digging

Most dogs spend large amounts of their waking time engaged in exploratory activities of various kinds, behavior that is essential for healthy development and normal environmental habituation. As the result of poor management or training, these natural exploratory interests may become exaggerated or misdirected into destructive activities, causing significant concern for dog owners. Some breeds (e.g., terriers) are more prone than others to dig. Likewise, highly active dogs (sanguine types) are more frequently

presented with digging problems than more relaxed and reserved dogs (phlegmatic types). In addition to predatory incentives stimulated by insects, worms, and other creatures living in the grass and soil, some digging dogs appear to enjoy the tug stimulation of pulling out shrubbery roots. Although some dogs may bury and recover buried food items (e.g., bones), this is not as common as one might suppose from the popular literature. Interestingly, wolves dig holes to cache food and urinate over areas where food has been dug up and removed (Harrington, 1981)—a behavior pattern not reported in dogs. Most common outdoor destructive complaints revolve around chewing and digging, operating under the influence of normal canine functional and motivational systems (Odendaal, 1996). Consequently, the causes of digging are numerous and varied, requiring careful history taking and observation. The owner should be asked the pertinent questions involved in any behavioral assessment, viz., the three W's (what, when, where) and the three H's (how long, how frequent, and how severe) (see *Behavioral Fact-finding* in Volume 2, Chapter 2). Some digging activity is simply part of having a dog, requiring in some cases that owners adjust their expectations rather than attempting to suppress all digging activity. Puppies, in particular, appear to enjoy the fresh smells and tastes of tender roots and freshly turned earth. In addition to the inherent pleasures associated with digging, a dog might use the activity as a somatic outlet for the release of various tensions involving boredom, frustration, and stress. As a result, excessive digging may become a compulsive outlet for dogs living under suboptimal conditions.

The location of digging activity can offer clues about its underlying causation. Digging along fence lines and near gates may stem from efforts to escape confinement due to territorial aggressive arousal, barrier frustration, fear, or separation-related distress. Digging near resting areas, under trees and shrubs, especially during the summer, may be motivated by an urge to expose damp earth just beneath the surface to roll in and cool down. To arrive at a successful solution, it is important that the motivational causes be identified and, if possible, removed or reduced before attempting to suppress undesirable digging. For example, bored dogs should be given additional exercise and play activities that provide adequate opportunities for stimulation, separation-reactive dogs need to learn how to cope more effectively with being left alone, and dogs digging to achieve improved thermoregulation should be provided adequate water to drink and a small plastic wading pool. Such dogs should also be provided with outdoor accommodations that provide better protection from heat when outdoors. When barrier frustration is identified as a factor, potential causes of frustration should be explored, for example, a high sex drive and desire to roam, the presence of roaming neighborhood dogs, or any other occurrences stimulating intense arousal and interest. Most digging problems appear to benefit from increased daily attention, obedience training, and exercise. Even after the aforementioned motivations and causes have been addressed, a dog may still engage in unwanted digging behavior. For many dogs, digging is inherently rewarding, providing a welcome distraction when left alone or understimulated. Because many dogs appear to possess a predisposition to dig, owners of persistent diggers should be advised to provide an area in the backyard set aside for digging activity. The digging area can be temporarily fenced off and baited with buried toys and biscuits. While digging is permitted in the designated area, excavations in other parts of the yard should be consistently discouraged. Some persistent diggers may not restrict their excavations to such areas, however, requiring the implementation of various behavior-modification efforts.

Dogs exhibiting an inordinate interest in digging should be consistently interrupted whenever they are observed engaged in the activity, and then encouraged to take up another activity such as ball play. Keeping the dog on a leash or long line can help facilitate this process. Some digging excesses can

be discouraged with a vocal reprimand ("Leave it") and appropriate leash prompt sufficient to interrupt the activity. A modified CO_2 pump with conditioned odor can be highly effective as a disrupter. Tossing a 30-penny shaker can near dogs while they are digging will rapidly interrupt and potentially stop its recurrence, at least so long as the owner is present. In addition to pennies, the can should contain a cotton ball scented with citronella-eucalyptus oil or commercial repellent. The conditioned odor (e.g., citronella-eucalyptus paraffin shavings) can be placed into holes, along with a startle-producing booby-trap device. For example, a motion-sensitive alarm can be sealed in a ziplock bag and placed into holes and covered with loose dirt and grass. A repellent effect might be achieved by mixing a tablespoon of cayenne pepper into a cup of sand, which is placed into a scented plastic bag that is tightly knotted and placed into a covered hole. Another method involves placing a remote-citronella collar in the hole or forbidden area and activating it when the dog digs or approaches the area too closely. In refractory cases, electronic training can be highly effective for suppressing digging activity (see *Electronic Training and Problem Solving* in Chapter 9). A stronger booby-trap arrangement is reserved for inveterate diggers. Several spring-loaded snappers are sealed in sliplock bags and buried at various levels together with citronella-eucalyptus wax shavings. As a result of such training, the conditioned odor may be used to help deter future digging activity by putting it other active holes.

Dogs that dig under fences can be deterred by attaching vinyl-coated wire fencing to the base of the fence and then burying it 6 to 10 inches underground. In cases where a physical modification of the fence is not practical, an electrified wire can be strung along the base of the fence to provide protection against escape efforts. Electric-fence controllers have been designed for dogs, producing a moderately strong electric shock when touched. When installing such devices, care should be taken not to allow it to come into contact with grass or other grounded objects. Another method involves stringing an electronic containment wire along the base of the fence. Either an electrical or spray boundary collar device worn by the dog should be sufficient to deter most escapists from digging or climbing over fences. Destruction of gardens and planted areas can be most effectively managed by setting up fencing that keeps dogs out of those forbidden areas.

PART 4: APPETITIVE PROBLEMS

Pica and Scavenging

Scavenging forbidden food and eating nonnutritive objects (pica) are common ingestive behavior complaints, requiring both behavioral and medical assessment (see *Pica and Destructive Chewing* in Volume 2, Chapter 9). Pica may present comorbidly with compulsive or hyperkinetic disorders, perhaps requiring adjunctive pharmacological intervention to manage successfully. White (1990), for example, found that one dog in his study of acral lick dermatitis (ALD) was also a rock chewer—a behavior that ceased together with the dog's ALD following treatment with naltrexone. In some dogs with pica, the appetitive-seeking system may be overly active, resulting in hyperarousal and excessive exploratory activity, chewing, and eating of nonnutritive items—signs consistent with hyperkinesis. Dogs showing a persistent appetite for nonnutritive items need to be carefully managed and supervised to prevent alimentary blockages or poisoning. A scavenging dog should be closely controlled on walks, perhaps keeping it on a fixed-action halter collar to turn its head more easily away from found food and garbage. At such times, the vocal signal "Leave it" is combined with a leash prompt strong enough to turn the dog's head away from the object. In addition to interrupting the scavenging response directly, the owner should encourage the dog to turn its attention away from the prized item by using various vocal signals

and auditory prompts (e.g., squeaker or smooch sound) and reinforcing the orienting response with a click and flick of the right hand to present a food reward. Such refocusing of attention away from the forbidden object toward the owner is consistently rewarded with treats of varying kinds and value taken along on walks. The dog also needs to be trained to release or drop anything it grabs. This phase of training is initially introduced with toys, with the dog being encouraged to take and release toys of increasing value in exchange for a proffered treat. This release-and-trade routine should be rehearsed and staged indoors and under controlled conditions before transferring it outdoors. As the dog learns to release the target item in exchange for food, the vocal signal "Out" is paired with the action as a discriminative stimulus. In addition to learning how to release toys, the dog should be trained to take them from the floor or hand on signal ("Take it").

Once the releasing and taking behaviors are under stimulus control, more compulsory safeguards are introduced to ensure that the dog avoids or rapidly releases forbidden items found on walks. The itinerary of the walk can be planted with forbidden items in advance, with their locations marked for easy recognition. An alternative method involves dropping forbidden items at various places on the outward leg of a walk and then training the dog to avoid them on the way home. Avoidance of forbidden objects is conditioned by combining directive leash prompts sufficient to turn the dog's head away together with various startle devices (e.g., the shaker can or modified CO_2 pump). As the dog approaches a forbidden object, the trainer shouts "Leave it", whereupon, if the dog fails to turn away on its own accord, a leash prompt is delivered that is strong enough to turn the dog away abruptly from the object. This procedure is repeated until the dog is reliably avoiding forbidden objects in response to the voice command "Leave it." Compliance to the limit-setting imperative is rewarded with affectionate praise and food as the dog returns to the trainer. Dogs with strong oral exploratory interests should also be provided with frequent opportunities to chase and retrieve toys taken along on walks for such purposes. To help generalize the avoidance response to off-leash situations, a shaker can or other startle-generating objects (e.g., throw rings) can be tossed near the forbidden object with the reprimand "Leave it!" Later, as the result of sensitization, a single shake of the can may be sufficient to deter future interest in the forbidden item. Transitioning from on-leash to off-leash control often requires that forbidden items be arranged to trigger some sort of booby trap, including drop cans and various remote-activated and behavior-activated electronic devices (see *Miscellaneous Devices and Techniques for Deterring Destructive Behavior)*. For example, a remote spray receiver can be concealed close to a forbidden object and activated by the trainer as the dog approaches it. In refractory cases of scavenging and pica, remote electronic collars delivering a spray or electrical deterrent can dramatically facilitate inhibitory training and aversive counterconditioning. Remote electronic collars can be highly effective, but they require significant owner instruction and preliminary training before use (see *Punishment and Aversive Counterconditioning* in Chapter 9).

Getting objects out of a dog's mouth once they have a hold can be difficult and sometimes dangerous. Many dog owners have been severely bitten in the process of prying a chicken bone out of their dog's mouth. Despite the risk presented by some dogs, the majority of dogs appear to allow owners to reach into their mouths to pull forbidden items out. Others may resist until the owner places a hand over the muzzle and gently squeezes the upper lip against the premolar teeth. Although commonly used, both of these maneuvers are risky, and it is far safer to train the dog to drop forbidden items on command and to back away (see *Aggression Associated with Guarding and Possessiveness* in Chapter 7). Dogs that persistently refuse to release dangerous objects (e.g., chicken bones) should be kept on a halter collar while on walks, as needed to prevent such behavior.

Coprophagy

Coprophagy is a common complaint presented by puppy and dog owners. A study using an owner questionnaire and involving 305 dogs living in Czech households found that 36% of the dogs ate feces—a habit that was more common among females (45%) than males (30%) (Baranyiová et al., 1999). Most owners are disgusted by the habit and are quick to punish such behavior. Although most dogs can be discouraged with routine prevention and training efforts, some dogs may persist in the behavior despite consistent training efforts or comply only so long as the owner is present. A wide variety of techniques have been devised to manage or suppress coprophagy. No one method is effective in all cases, but most dogs eventually respond to a combination of management and training efforts. Since coprophagia is sometimes associated with disease, the dog should be given a veterinary examination to exclude a medical cause. Persistent coprophagy is a serious problem, not just because it is potentially a health risk for the dog, but because it may threaten the human-dog bond as a result of owner displeasure and disgust with the habit. Consequently, coprophagy should be treated with sensitivity and not summarily dismissed as a normal thing that dogs do and something the owner should get over and learn to live with.

Hot Sauce, MSG, Breath Mints, and Other Concoctions

Aside from interactive punishment, the most common method used to discourage interest a dog's in feces is to contaminate the feces with hot sauce (O'Farrell, 1986). Unfortunately, the approach is rarely effective because the dog simply moves on to a fresh deposit that has not been contaminated. Recognizing the obvious shortcomings of coating feces with hot sauce, Houpt (1991) has suggested that the hot sauce be injected into the feces with a syringe and hypodermic needle. The operative assumption is that by injecting feces the dog will be unable to detect the hot sauce until it is too late, causing it to avoid untreated feces as well because it can never be sure which pile contains the repellent. However, given the extraordinary acuity of a dog's nose, it is unlikely that most dogs would be fooled by such a trick. Furthermore, even if the odor could be effectively masked inside feces, the exercise would probably still be in vain since dogs usually swallow the feces in a single gulping action, not leaving much time for the repellent to disperse into the dog's mouth before it is swallowed. Finally, many dogs will bolt down feces sloshed with hot sauce, showing little sign of aversion to the fecal condiment.

Other common remedies are given to dogs to eat in order to make feces less attractive, including meat tenderizers, monosodium glutamate (MSG)-based products, sulfur, and breath meats. There is little evidence that such methods actually work, but positive anecdotal claims have been made for meat tenderizers containing papain and products containing MSG (Carlson and Giffin, 1980). Although the usefulness of MSG for the control of coprophagy has not been demonstrated, it is frequently recommended as a way to make feces less attractive to dogs. Grinding breath mints into a dog's food has also been suggested for the control of coprophagy (Taylor and Luescher, 1996), but no data or rationale are offered to explain the treatment. Other foodstuffs that have been suggested include canned pumpkin, pineapple juice, and anise extract. Both canned pumpkin and pineapple juice are a source of papain. Sulfur-containing foods (e.g., brussels sprouts or cabbage) might be tried, based on a report suggesting that small amounts of sulfur may make the feces less attractive to a dog (Hubbard, 1989). Another alternative source of supplementation is sulfur-containing amino acids (e.g., cystine and methionine) or foods containing high levels of the same. Ferrous sulfate (iron) has also been recommended as way to adulterate feces and make it less palatable (Mugford, 1995). The addition of cooked liver (a good source of iron) to a coprophagous dog's diet might provide some benefit. Adding fiber (e.g., cellulose-containing vegetables like cooked carrots, green beans, and broccoli) to the diet may alter the texture

and smell of the feces sufficiently through natural fermentation to make it less attractive to dogs. Finally, *The Merck Veterinary Manual* (Fraser et al., 1991) recommends feeding a high-protein/low-carbohydrate diet supplemented with vegetable oil twice daily, claiming that such a diet can control the problem (in many cases) within 2 months. Adding chemicals and supplements to a dog's diet can be potentially harmful and should be done only under the supervision of a veterinarian.

Nutritional and Dietary Changes

Because a dog might be attracted to partially undigested food remaining in feces, adjusting the diet in terms of its schedule, amount, and nutrient quality may be helpful. Consideration should also be given to adjusting the proportion of protein to carbohydrates and fat in the dog's diet. When possible, coprophagous dogs should be fed high-quality food provided on a multiple-opportunity feeding schedule (two or three times a day, depending on the age and needs of the dog). In addition, the diet might be supplemented with muscle or organ meat (liver or heart) on a temporary basis. Since a coprophagous dog may be seeking B vitamins in the feces, a vitamin supplement, rice bran, or brewer's yeast should be considered (Cloche, 1991). Lastly, a fish-oil supplement might also be considered and added to the dog's diet in appropriate amounts. Many practitioners recommend adding a meat tenderizer containing papain to the dog's diet. Papain can also be obtained in a pure form from most health-food stores. Dogs that prove responsive to commercial meat tenderizers should be given a trial period on papain, either from a natural fruit source (e.g., canned pumpkin) or from an extract powder mixed into their food. Alternatively, products containing a broad spectrum of digestive enzymes (e.g., Prozyme) seem to be effective in many cases.

Preliminary Training

The dog should be prevented from having access to feces for at least 2 weeks, during which time dietary changes and supplementation can be introduced, if warranted, together with supplemental play, exercise, and reward-based obedience training. Ideally, a coprophagous dog should be walked on leash and distracted from feces by calling its name and smooching or squeaking to interrupt interest in the feces and divert its attention toward the owner. As the dog turns away from the feces, it is called ("Come") and rewarded with appropriate encouragement and rewards. The yard should be kept clean of feces. After eliminating, the dog should be praised and a small biscuit tossed out in front of it to pick up. Small biscuits can be covertly dropped during the walk for the dog find on the way back. Likewise, the yard can be seeded with biscuits for the dog to find when let out to play. If the dog ignores efforts to get its attention and approaches the feces, the reprimand "Leave it" is spoken in a firm tone, followed by a directive leash prompt sufficient to turn it away from the feces and toward the owner. The procedure is repeated until the dog turns away from the feces or avoids it in response to the voice signal alone. Additional training may require the use of disrupter-type stimuli, such as the toss of a 30-penny shaker can or burst of air from a modified CO_2 pump. Again, exposure is repeated until the dog shows an active avoidance of feces while on walks.

Booby Traps

Coprophagous dogs should be prevented from eating feces for at least 2 weeks before being exposed to booby-trapped feces. As already discussed, a dog's olfactory abilities mitigate the effectiveness of repellents as deterrents. Unless every feces is consistently treated, dogs will simply avoid stools treated with the repellent and look for ones that are not treated. A motion-activated alarm sealed in a zip-lock bag can be rigged so that it is triggered whenever the dog disturbs the stool. A spring-loaded snapper (see *Caps and Snappers*), which causes a small cap to explode when it is disturbed, produces a stronger startle effect and deterrence. Such "stool mines" can be hidden under the feces. The cap is glued to the underside of a 3-inch square of light cardboard. The snapper is loaded, and the card-

board is put on the ground with a stone placed on top to keep it in place, thereby preventing the loaded snapper from kicking up and going off. A fresh stool is placed on top of the arrangement, and telltale signs of cardboard are covered with bits of loose grass and dirt. For safety sake, if not placed on the underside of paper or cardboard, the snapper should be sealed in a zip-lock bag to prevent flying debris from reaching the dog.

Cat droppings are a favorite with some allocoprophagous dogs. To prevent such problems from developing in the first place, dogs should be kept away from litter pans. In some cases, a cat door or small passage cut through the base of the door can provide the cat with access to its litter but block the dog from getting inside the room. Alternatively, the door can be wedged open between two rubber doorstops, leaving an opening wide enough for the cat to get through, but blocking the dog's access. In the case of dogs exhibiting an established appetite, the first step is to prevent access to cat feces for at least 2 weeks before initiating additional training activities. Training efforts should be first performed on leash to establish an avoidance toward the litter pan, followed by the shaker-can procedure described previously. Since booby trapping risks exposing the cat to accidental stimulation, such devices are not appropriate as deterrents. In situations in which the cat's litter pan cannot be kept out of the dog's reach, electronic devices designed to activate an electrical or spray stimulus worn by the dog can be arranged in the vicinity of the litter pan. When the dog approaches too closely, the collar is activated, causing it to rapidly learn to avoid the situation.

Electronic Training

Electronic training can be used efficaciously to control coprophagy refractory to other methods of control. Both remote electrical or spray stimulation can be effective. The aversive stimulus is delivered at the moment the dog reaches for the feces, but, ideally, before it is picked up. To be effective, the training should be staged in various situations where the dog has eaten feces in the past. An electronic collar should only be used to deliver deterrent levels of electrical stimulation after safety training is performed with low levels in the context of reinforcing attention control, recall, quick-sit, stay, and halt-stay exercises (safety training). When used to deter coprophagy, the first exposure in which the electrical stimulus (ES) is paired with feces should be of a sufficient strength to produce an immediate and durable inhibition of the activity. The level of stimulation is determined by the dog's degree of sensitivity and tolerance for the ES. Most dogs rapidly learn to avoid feces following a momentary "nick" (100 to 400 msec) of moderate to strong ES. Increasing the level of electrical stimulation gradually is problematic, since the dog may rapidly habituate to each level of ES, requiring a much more aversive event in the end to achieve the desired deterrence effect. Further, a low-level ES not only may invite or perpetuate an already established approach-avoidance conflict toward feces or risk producing vicious-circle behavior in dogs that are not deterred sufficiently by the ES, but may persist or increase the activity in the presence of the aversive event. Such dogs may learn to eat the feces rapidly, thereby foiling the owner's control efforts. Such a vicious-circle effect is often observed in the case of dogs exhibiting persistent and long-standing coprophagy. As the dog's training progresses, it should be exposed to progressively natural conditions where coprophagy might occur in the owner's absence. At such times, dogs may be tempted to find and eat forbidden feces. A well-timed electrical or spray stimulus delivered from a remote location can be very effective to deter such behavior. Until coprophagy is fully suppressed, the dog should not be let in any situation where it might find feces to eat.

Taste Aversion

Many laboratory studies have demonstrated that animals exposed to some nausea-producing event after eating consequently develop a lasting aversion toward that food item (Garcia et al., 1966). This aversion effect often occurs after a single trial and even after a long delay between eating and exposure to the nausea-producing agent. In some experiments, the nausea-producing agent was not given for

several hours after the animal had eaten the food. Two aspects of taste aversion are extraordinary when compared to how associative learning usually takes place:

1. A strong and lasting aversion may occur after a single exposure.
2. The aversion develops even though the conditioning events are not closely associated with one another in time.

These characteristics are inconsistent with the usual way in which classical conditioning is believed to take place, requiring that conditioned and unconditioned stimuli be repeatedly paired together in a forward and closely contiguous fashion. The discovery of taste aversion had a profound impact on learning theory (see *Prepared Connections: Taste Aversion* in Volume 1, Chapter 5).

Taste aversion is not the same thing as the conditioned repulsion produced by aversive exposure and sensitization to olfactory and gustatory deterrents like hot sauce and commercial spray repellents. For instance, letting a dog first sniff and then squirting a repellent into its mouth is not consistent with recognized protocols for producing taste aversion (Gustavson, 1996). The procedure described by Beaver (1994) may produce significant revulsion, discomfort, and a conditioned repulsion toward the smell and taste of the substance, but despite the procedure's indisputable capacity for producing aversive arousal and sensitization, it will probably not produce a true taste-aversion effect (see *Taste Aversion* in Volume 1, Chapter 6). However, the method may rapidly cause the dog to resent having its muzzle handled or possibly make the dog refuse to let the owner open its mouth in the future, especially if the procedure is performed repeatedly. Along a similar vein, the practice of spraying concentrated or dilute repellents (e.g., lemon or vinegar) into a dog's face as a deterrent for misbehavior should be avoided, since such treatment may irritate the eyes, produce an aversive state that continues long after the unwanted behavior ceases, and perhaps overlap with more acceptable behavior and hinder efforts to reward it. Repeatedly squirting a dog in the face with dilute repellents or even plain water may rapidly cause it to become avoidant toward the owner. Rather than suppressing the unwanted behavior, dogs often learn to perform the target behavior safely outside of the owner's squirting range. In general, olfactory startle conditioning is preferred for developing chemosensory deterrent signals. Once conditioned, the odor can be used to mark forbidden objects, thereby providing the dog with a warning signal helping it to avoid booby traps set up in close association with the marked objects.

Although the efficacy of taste aversion for the treatment of refractory coprophagy remains controversial (see *Tolerance for Nausea and Taste Aversion* in Volume 2, Chapter 9), the "coprophagiac" might be beneficially treated with a series of treatments using a taste-aversion procedure, especially in cases where electronic training is not feasible or appropriate (e.g., dogs exhibiting behavioral counterindications advising against such training). Taste aversion is most effective in cases involving relatively novel food items, but this criterion is not an absolute. According to Gustavson (1996), conditioned taste aversions can be established with flavors that the animal has been repeatedly exposed to over a long period. Common emetics like ipecac and hydrogen peroxide do not perform as effectively as other taste aversion agents, since they may fail to produce nausea. The chemicals used in taste aversion must produce nausea but not necessarily vomiting. A variety of chemical substances can be used to produce nausea in dogs (see Gustavson, 1996). Taste-aversion conditioning can be established by contaminating feces in advance with the selected nauseant or inducing nausea immediately after the dog ingests feces (Table 2.2).

Caution: Taste-aversion conditioning involves administering potentially poisonous and hazardous chemicals to a dog and should be performed only under the advisement and supervision of a veterinarian familiar with the procedure and its risks, including potential adverse behavioral side effects (see Hansen et al., 1997).

PART 5: CRATE TRAINING

Crate training should always be governed by a philosophy of constructive confinement, sig-

nifying that some purposeful training objective is being accomplished by its use. In addition to the criterion of purposeful training, constructive confinement entails that a plan be devised to ensure the eventual release of the puppy or dog from confinement. Without such considerations, the crate can easily become an abusive training tool and a way of life for the dog. Even the most benign and beneficial training tool can become abusive and cruel if excessively or improperly used.

SELECTING A CRATE

Choosing the right crate involves several considerations. Two kinds of crates are typically used for house-training purposes. The most frequently used crate is constructed of heavy-

TABLE. 2.2. Program for persistently coprophagous dogs

1. Coprophagous dogs should receive a thorough veterinary exam to rule out a medical cause.

2. A broad-spectrum digestive enzyme product (e.g., Prozyme) should be considered.

3. Dietary changes may also be helpful, even in cases where the dog is eating a premium diet. Feeding more than once a day may be beneficial in some cases.

4. A determination of when and where the dog eats its stool should be established. Also, information should be recorded regarding the history of the problem. For example, when did the behavior first appear and what sort of things have been tried already to control it?

5. Possible quality-of-life contributing factors should be identified, such as excessive confinement, inadequate play or exercise, environmental stressors, and nutritional deficiencies.

6. Many dogs that exhibit coprophagy also appear to exhibit poor impulse control and attentional abilities. These deficits are addressed through integrated compliance training.

7. The owner is encouraged to walk the dog away from the yard for 2 weeks. During this period, the dog is prevented from approaching or picking up feces by keeping it on a leash and collar (halter type, if necessary). The dog's interest in feces is interrupted with diversionary efforts to capture its attention (e.g., calling its name or squeezing a squeaker) or by using directive signals ("Leave it") and leash prompts sufficient to turn the dog away from the feces. If the dog averts its attention away from the feces, the behavior is bridged ("Good" or click) and reinforced with a food reward. Gradually, the dog is trained to turn from feces and orient on the owner to obtain a food reward.

8. A small biscuit is given to the dog as soon as it leaves the house, and periodically thereafter pieces of biscuits are tossed down for the dog to find in the grass. In addition, the owner can secretly drop biscuits along the way, which the dog is encouraged to find on the way back home. The goal is to encourage the dog to focus on searching for food rather than feces while on walks. As the dog's behavior improves, the number of treats left for it to find can be gradually reduced and faded out. A similar search-and-find game can be set up in the backyard.

9. In cases where diversionary efforts fail to secure the dog's attention, more potent disrupter-type stimuli may be necessary to interrupt the coprophagous interests. A shaker can is often highly effective if thrown at the instant a dog approaches feces. The forceful hissing of the modified compressed-air pump can be highly effective, with the added benefit of blowing the feces out of the dog's reach. The modified compressed-air pump is preferred to excessively loud and startling devises, such as the compressed-air nautical horn.

10. After 2 weeks, various booby traps are introduced to discourage coprophagy when the dog is left alone in the backyard. In general, the yard should be kept clean, with the exception of one or two piles that are left with a booby trap attached to them.

11. In refractory cases, electronic training can be very helpful but should be considered only after the above preliminary efforts have been implemented. Electronic collars delivering electrical or chemical stimulation provide an exact and timely event at a distance—a critical factor affecting the effectiveness of inhibitory training.

12. A conditioned taste-aversion procedure should be considered as a last resort.

gauge metal wire. The crate should be of good quality and sturdy construction. Many dogs have seriously injured themselves attempting to escape from poorly designed and built crates. The best crates are made from panels of 1-inch grid work, but those made with 1- by 3-inch grid panels are usually sufficient for the average puppy. Another type of crate often used for house training is made of plastic and designed for air travel. The plastic travel crate can be made more comfortable by turning it upside down so that the side panels of open grid work are located toward the bottom. This arrangement improves air circulation and gives the puppy a better view of the surroundings while lying down.

An important consideration in choosing a crate is its size. The crate should be big enough to contain an adult dog with enough room for it to stand, lie down comfortably, and turn around. In many cases, this will be a medium to large crate, too big for house-training purposes. Most pet stores stock cage dividers that can be inserted inside the crate to produce the desired dimensions. In addition to a crate, an exercise pen should be obtained. The pen is composed of several interlocking panels that can be adjusted to fit various areas and size needs. It provides greater freedom of movement than provided by the crate, but prevents a puppy from wandering around too much until it is ready for such freedom. If a puppy must be left for extended periods, the crate is kept open and placed inside the holding pen or small puppy-proofed room covered with several layers of newspaper. The puppy should always be provided with a supply of fresh water to meet its needs for the day. Excessive restriction of water does not hasten good elimination habits, but could compromise the puppy's health, perhaps predisposing it to develop urinary tract problems (e.g., cystitis). In addition, puppies deprived of water may drink excessively when finally given an opportunity to drink and then rapidly excrete the excess. Once puppies are successfully crate trained, they can be gradually given more freedom of movement, first in an exercise pen, then the kitchen, and finally the entire house, as they mature and become fully reliable.

Guidelines for Successful Crate Training

Most puppies can learn to tolerate crate confinement with minimum distress, provided that it is introduced properly (Table 2.3). The all-too-common practice of setting up the crate and then shoving the uncooperative puppy inside of it to whine, bark, and to attempt to escape from it only risks conditioning a negative and reactive response toward confinement. Remembering that first impressions are enduring, such practices should be avoided. To produce a more positive and minimally stressful attitude toward crate confinement, several simple precautions should be taken. The crate should be set up in a well-socialized part of the house and kept open for the puppy to explore and enter on its own initiative. Putting soft bedding and toys in and around the crate can help to make it more attractive for a wary puppy. Concealing treats in bedding can further entice a puppy to explore the crate and develop a positive attitude toward it. Fetch games should be played around the crate, occasionally tossing the ball into the crate and encouraging the puppy run after it. Also, highly valued chew toys can be put in the crate at various times during the day, further increasing the attractiveness of the crate. Meals and water can also be given near or inside the crate.

Once a puppy is habituated to the presence of the crate and shows a willingness to enter on its own, further training efforts should be introduced. The following instructions are particularly useful for desensitizing and training the resistant puppy to enter and accept crate confinement.

Step 1

Small bits of an appealing food item are tossed in front or just inside of the crate. This procedure is repeated several times, gradually requiring that the puppy move closer and finally poke its head inside the crate. A familiar rug or blanket should be placed inside the crate to make it more attractive and to muffle potentially startling noises that may be produced when the puppy steps on the pan. As the puppy's confidence improves, the treats are tossed further back in the crate until the

Table 2.3. Constructive crate confinement

Do not crate a puppy wearing a collar.
Place the crate in a well-socialized part of the house.
Ensure that the crate is free of drafts and excessive heat.
Do not confine a puppy in the basement or garage.
Never use crate confinement as a form of punishment.
Never allow children to tease or play with a puppy in a crate.
Never attempt to confine a puppy for periods that exceed its ability to control elimination functions.
Provide the puppy with adequate water for its needs during the day.
Do not allow crate confinement to become a way of life.
Never use the crate as a permanent "steel straitjacket" for unresolved behavior problems.

puppy fully enters. As the puppy turns, it is tossed an additional treat, but it is not prevented from leaving the crate.

Step 2

The treat should be tossed with an exaggerated wave of the arm, with the goal of training the puppy to respond to the movement as a prompt to enter the crate. Occasionally, the gesture is made without tossing a treat, causing the puppy to move into the crate and turn about before it is given the expected reward by hand. Once the puppy reliably responds to the prompt, a vocal signal (e.g., "Crate") can be presented in combination with it. Now, as the puppy enters the crate on signal, it is rewarded and the crate door briefly closed and the puppy given several treats through the crate door. After several seconds, the puppy is released and the procedure repeated, progressively requiring that it stay in the crate for longer periods before being released. The puppy's tolerance can be improved by providing it with a beef bone or some other highly desirable chew toy (e.g., a hollow rubber toy smeared on the inside with peanut butter). It is important to vary the duration of confinement, with graduated exposures, for example: 5, 15, 25, 5, 30, 15, 45, 30, 5 seconds, thereby introducing a beneficial element of positive prediction error and reward. As the puppy learns to enter the crate and accepts brief confinement without protest, longer periods of confinement can be introduced as well as confinement in different household locations (e.g., kitchen, bedroom, and living room), starting with a few seconds and gradually building up to 30 minutes or more, as its tolerance for confinement improves. Puppies should be crated in the bedroom at night and left in the kitchen during the day. In addition to leaving puppies with a tasty toy, the owner should provide the puppy with a scented towel or a few items of soiled clothing (e.g., T-shirt and socks) put inside of a knotted pillow case.

Step 3

Most dogs and puppies accept the aforementioned crate-training process without much anxiousness or resistance. Occasionally, a difficult dog will refuse to enter the crate no matter what efforts are employed to ease its resistance. In such cases, a leash or an active-control line is set up and passed through the opposite crate panel. The puppy or dog is hooked up and prevented from pulling away from the crate and is then slowly maneuvered closer to it through several steps of reward-based training and counterconditioning. Posture-facilitated relaxation (PFR) training may be used to help reduce resistant behavior by training the dog to relax in response to physical restraint (see Appendix C). Ideally, such

dogs should be calmed before entering the crate. In some cases, mild to moderate pulling force may be needed on the control line to get the dog into the crate, but such force should be used only as a last resort. Once in the crate, the dog is repeatedly rewarded with food and reassured with affectionate praise and is immediately released. The procedure is repeated on a control line until the dog shows no resistance or hesitancy about entering the crate. In some cases, a remote feeder can be set up at the opening of the crate, delivering a soft food with a faint safety odor (e.g., orange). As the dog approaches the front of crate, the feeder is activated. Gradually, the feeder is set up farther back in the crate, requiring that the dog enter to obtain the food (see *Systematic Desensitization* in Chapter 3). The feeder enables the trainer to provide a continuous flow of repeated reward events while near the dog or while in another room and watching the dog's behavior via a remote camera.

Some puppies and dogs may protest against confinement with persistent barking and intermittent whining, despite gradual and patient desensitization efforts. In such cases, a squeaker can often be helpful as a means to interrupt barking or other vocalizations. After a brief exposure to the squeaker and clicker in the context of attention and sit-stay training, the stimuli can be used to help control excessive vocalization in the crate. As the puppy orients to the squeak sound and stops barking, the break in vocalizing is bridged with "Good" or a click, and the puppy is thrown a treat, whereupon a differential reinforcement of other behavior (DRO) schedule of reinforcement is introduced, such that a bridge and treat is delivered every so often (e.g., 2 to 5 seconds), provided that the dog does not bark during the DRO period (see *Barking* in Chapter 5). Gradually, the DRO period is increased and the vocal signal "Quiet" is paired with the initiation of every DRO period. Alternatively, the barking can be brought under stimulus control by clicking and tossing the dog a treat on each occasion it barks. As the dog's barking turns to the control of food, the vocal signal "Speak" is timed to occur just before or as the dog begins to bark, followed by the bridge and food reward; conversely, barking off cue is followed by "Quiet" and the loss of reward (response cost). At the earliest opportunity, the trainer should prompt the dog to bark with "Speak" and then bridge and reward the behavior.

As the barking comes under stimulus control, the trainer can initiate time-outs of variable duration in response to barking off cue, thereby linking the loss of social contact with barking and its recovery with not barking. During the time-out, the dog can be ignored in the crate or the trainer can leave the room briefly (e.g. 20 to 30 seconds), requiring that the dog not bark for a brief period before bridging, returning, and rewarding the behavior. As the contingencies become clear to the dog, a drop can is set up and suspended above the crate with a line of dental floss. The drop can is arranged to fall and strike near the crate or on top of it, depending on the dog's temperament and response to such startle. The release of the can is associated with a clipped and subdued "Quiet," perhaps mediating a more rapid inhibitory association while at the same time reducing the level of startle produced by the event. (See the discussion of prepulse inhibition effects covered in *Interrupting Behavior* in Chapter 1). The strength of the event is determined by the height at which the can is dropped and the weight of the can used. In dogs with relatively high-auditory-startle thresholds, a 30-penny can suspended from the ceiling and dropped on top of the crate may be necessary, whereas dogs exhibiting low-auditory-startle thresholds may show an adequately strong response to a seven-penny can dropped 2 feet from the floor. An expedient way to discourage protest vocalizing at bedtime is to say "Quiet" and then to rattle or drop a partially suspended seven-penny shaker can, letting it fall near the crate or on top of it. The shaker should fall forcefully enough to disrupt the behavior but not evoke an excessive startle or fear reaction. If the puppy persists in the barking behavior, the can be dropped from a higher level or replaced by a 30-penny can. As a result of such training, the startle response to the rattling sound is potentiated, causing the puppy to respond to the slightest rattle of the can held by owner or produced by jiggling the suspended drop can. In the case of puppies

overly sensitive to the shaker can, pennies can be put inside of a plastic vitamin bottle, thereby producing a shaker that is less noisy and startling.

Before carrying out such procedures, special care should be taken to make sure that a dog's or puppy's protests are not due to fear of confinement or separation distress. Anxious dogs and puppies need to be handled carefully, reducing their fears of crate confinement gradually by means of gradual exposure, counterconditioning, and PFR training. Crate confinement may significantly exacerbate the distress and emotional reactivity associated with separation distress (Borchelt and Voith, 1982). Separation-reactive dogs sometimes become extremely reactive when left alone in a crate, resulting in the loss of eliminatory control and panic-stricken efforts to escape. Separation-reactive and separation-phobic dogs have seriously injured themselves in their frantic efforts to escape confinement when left alone. Aggressive threats and attacks are not uncommon while an unwilling dog is being forced into a crate. If a puppy's adverse reactivity to confinement is suspected to be due to separation distress, it is imperative that appropriate training be carried out to resolve it (Voith, 2002). To prevent separation-distress-related problems, the puppy should be exposed to separation-desensitization training (see *Attachment and Separation Problems: Puppies* in Chapter 4). Such training should be carried out in parts of the house that hold positive emotional associations for the puppy, e.g., the bedroom or kitchen. Allowing a separation-distressed puppy to whimper and whine for long periods without respite should be avoided. Extended periods of separation distress, especially when occurring under unfamiliar circumstances, may predispose sensitive puppies to become overly reactive to routine separations as adults.

By gradually increasing the separation duration while confined in the crate, the puppy learns to experience the crate as a safe situation predicting the owner's eventual return. The owner should be advised of both the benefits of constructive crate confinement and the potential adverse side effects of excessive confinement. Dogs exposed to long periods of daily crate confinement should receive compensatory exercise, play, and focused attention in the form of reward-based training. A record of the amounts of time (day and night) that the puppy spends in the crate should be kept (Figure 2.7), with the goal of gradually reducing the time spent in crate confinement as training objectives are reached. In summary, constructive crate confinement can be employed as a humane and effective training tool, but it needs to be carefully introduced and never used in the absence of proper training or as an expedient way of life.

Dangers of Excessive Crate Confinement

The advocacy of crate confinement as a way of life, sometimes involving 16 to 18 hours a day, for dogs is inconsistent with their biobehavioral needs and may lead to emotional and behavioral deterioration over time. Some puppies and dogs appear to develop an inordinate attachment with their crates, sometimes preferring to be in their crates rather than with the owner. The daily repeated exposure to the sterile environs of the crate may significantly undermine a developing dog's ability to habituate and adjust to the wider domestic social and physical environment. Although most puppies initially respond to crate confinement as a stressful state of affairs, with repeated exposure stress and aversion gradually give way to an odd attraction to confinement. This gradual attraction to crate confinement appears to occur in association with increased feelings of security, safety, and comfort, rather than increasing levels of vulnerability and insecurity, as one might expect from a condition of entrapment.

Bonding with the Crate

One possible explanation for this paradoxical effect is provided by opponent-process theory (see *Opponent-process Theory and Separation Distress* in Volume 2, Chapter 4). The lengthy exposure to crate confinement provides a situation in which separation distress and other reactions associated with vulnerable isolation

eventually give way to opponent affects of comfort and safety, that is, the exact opposite to the distress and vulnerability initially evoked by crate confinement. Over the course of repeated exposures, the initial adverse reactions to confinement and isolation become weaker and gradually are overshadowed by opponent arousal involving feelings of enhanced security and contentment. In addition to providing emotional arousal incompatible with aversion and efforts to escape, these hypothesized opponent responses may provide a counterconditioning effect, further restraining and reducing aversive arousal asso-

ciated with crate confinement. So far, this opponent-processing analysis does not sound like much of a problem for a dog until one considers how it may interfere with the formation of a satisfying attachment and bond between the owner and the dog. A significant aspect of the attachment object is the provision of comfort and safety, that is, security. For dogs exposed to excessive crate confinement or home environments lacking sufficient consistency and order, their search for comfort and safety may gradually turn from the family and home to the crate. Such dogs may develop a powerful bond and dependency upon the crate as a space of comfort and safety. According to the foregoing opponent-processing analysis, behavioral restraint in association with confinement may result in opponent affects associated with enhanced comfort and safety (nurturing), thereby producing a source of intrinsic reward, security, and contentment that may support passive activities occurring in association with crate confinement. As such, crate confinement minimally meets the three interactive criteria required for establishing a bond: (1) dominance (limit setting by force or threat of force), (2) leadership (prompting and rewarding alternative behavior), and (3) nurturance (comfort and safety obtained in association with deference (criterion 1) and cooperation (criterion 2). Interestingly, when dogs that have been trained to sleep in an isolated part of the house in a crate are allowed to sleep in a bedroom, they often show signs of acute distress, including increased exploratory activity, agitation, and inability to calm down and sleep. In addition, some of these dogs exhibit excessive drooling, become diarrheic, lose bladder control, and show other changes consistent with the behavioral and autonomic sequela associated with separation distress. This reactive behavior is often persistent and requires that the dog be slowly adjusted to sleeping in the bedroom at night.

So, as many owners say, it may be truer than expected that some dogs do, in fact, love their crates, perhaps in some cases more than they love the owner. According to the crate-bond hypothesis, in the absence of a secure and gratifying attachment between the owner and dog, a crate bond may preempt or interfere with the formation of a human-dog bond, possibly setting the stage for the development or exacerbation of a variety of bond-related behavior problems (e.g., separation-distress and owner-directed aggression). Interestingly, in this regard, a subgroup of social aggressors is particularly reactive when in their crates or when disturbed while engaged in activities phenomenally similar to those associated with the security afforded by crate confinement (e.g., resting). Excessive crate confinement may generally sensitize and lower reactive thresholds in predisposed dogs to signals of punishment (threat or loss of comfort) and uninvited social contact, resulting in signs of increased intolerance, irritability, and social incompetence. Excessive crate confinement may cause such dogs to become inordinately sensitive to touch contact and interference while in resting states, possibly because learning conducive to competent impulse control in response to intrusions upon such states of heightened comfort and safety requires direct interaction and tactile contact between the owner and dog, but the crate effectively blocks such interaction and learning. Although the dog may get adequate auditory and visual stimulation while in the crate to offset sensitizing effects of sensory deprivation, tactile stimulation is entirely restricted, providing the basis for a sensitization effect that may increase irritability and intolerance for frustration while lowering aggressive thresholds in response to training. Compensatory tactile stimulation in the form of PFR training is incorporated into the treatment of such dogs in order to provide the necessary direct stimulation to reduce sensitization effects and to organize expectancies incompatible with threat or loss of comfort.

Adverse Effects of Excessive Confinement

Social and environmental adaptations occurring early in life appear to moderate sensorimotor thresholds and homeostatic set points to environmental and social stimuli. Inadequate exposure to varied and complex environmental circumstances and social experiences, traumatic or abusive handling, or exposures lacking sufficient order and consistency may significantly alter reactive fear and

anger thresholds, causing dogs to become progressively reactive (fearful or aggressive) or intolerant of novel or complex demands put upon them. Rearing under laboratory conditions of sensory restriction and social isolation causes a broad spectrum of devastating behavioral effects. Dogs raised to maturity under conditions of social and environment restriction tend to become increasingly excitable, reactive, and disorganized in response to environmental change. Early work carried out by Melzack (1954) identified a cluster of deleterious emotional and cognitive effects resulting from excessive sensory restriction and confinement of developing dogs. These dogs showed a persistent and excessive hyperexcitability to environmental change, reflected in durable changes in brain electrical activity (Melzack and Burns, 1965). The slightest deviation from their accustomed social and environmental conditions resulted in a dramatic increase in activity, often culminating in the expression of whirling fits. In addition to impulse-control dysregulation, restricted dogs often exhibited extreme attention deficits, preventing them from selectively attending to environmental stimuli in an organized way. Instead of exploring and interacting with objects, such dogs raced from one thing to another. Restriction-reared dogs showed a pronounced inability to learn simple avoidance tasks and reacted abnormally to painful stimuli (Melzack and Scott, 1957).

According to Melzack's analysis and model, environmental stimulation is selectively filtered at the "earliest synaptic levels of sensory pathways" in accordance with information derived from past learning—an early articulation of the sensorimotor-gating hypothesis (see *Prediction and Control Expectancies* in Chapter 1). Melzak's theory suggests that the loss of attention and impulse control exhibited by severely restricted dogs is due to a failure of the restrictive environment to provide sufficient opportunity for the dog to acquire a predictive network of associations with which to filter relevant sensory input from irrelevant static. The central nervous system of such dogs appears to crash under the overload of a sensory bombardment resulting from the restricted dog's inability to competently filter out relevant from irrelevant sensory data and to contextualize it in conformity with past memories and experiences (prediction and control expectancies). As the result of adaptive learning, the dog acquires a cognitive and emotional interface of prediction-control expectancies that rapidly appraises the significance of sensory input via a comparator function sensitive to the detection of discrepancies between what the dog expects to occur and what actually occurs (see *Prediction Error and Adaptation* in Chapter 10). Relevant information is selected from irrelevant information based upon the input's significance to operative control incentives ongoing at the moment. Sensory input that deviates from established control expectancies, resulting in surprise (reward) or disappointment (punishment), is of particular importance for the development of organized behavior. Information resulting in surprise and the avoidance of disappointment is preferentially sought in the process of learning. In addition to prediction errors related to control incentives and expectancy modules (e.g., surprise), dogs are also sensitive to discrepancies occurring in association with novelty and startle. However, instead of reacting to novelty or startle with disorganized output as in the case of Melzack's restrictively reared dogs, well-trained and socialized dogs respond to such stimuli with appropriate hesitation and curiosity before choosing a course of action. Finally, unlike restricted dogs, which respond to aversive stimuli without a clear appreciation of the event's significance as a threat, well-adjusted dogs respond to unconditioned aversive stimuli with forbearance, escape, or aggression, as appropriate and most likely to control the event successfully, perhaps in accord with a rapid cost-benefit analysis of available control modules and probable outcomes.

Even in cases where puppies have been previously well socialized, they may become progressively reactive to environmental stimuli and handling if kept under conditions of sensory and social deprivation (Fox, 1974). In such cases, sensory restriction and social isolation appear to degrade or reverse the benefits of early socialization. Dogs need a balance of sensory input to achieve behavioral homeostasis. Depending on tempera-

ment traits and early experience, environments producing too little or too much stimulation may produce an adverse effect. Environments producing too little stimulation and variety may predispose dogs to develop behavioral adjustment problems associated with intensified efforts to increase stimulation and gratification. Dogs presenting with hyperactivity are often affected by stimulation-seeking excesses, especially attention-seeking behavior that appears to continue unabated, even after the dogs get large amounts of social contact and stimulation. Environments producing too much stimulation and variety may produce changes in behavior in the direction of compulsive excesses, that is, behavior aimed at modulating excessive stimulation. Most dogs are organized with a sufficient degree of behavioral plasticity to adapt to environmental changes involving increases or decreases in stimulation, on the one hand, and increases or decreases in frustration or anxiety, on the other (adaptive types). These stable and adaptive dogs are differentiated along an extraversion-introversion continuum: the sanguine (stable extravert) and phlegmatic (stable introvert). However, some dogs, as the result genetic predisposition, adverse early experiences, or neurotogenic learning may become progressively reactive to increases or decreases in environmental stimulation and changes producing frustration and anxiety (reactive types). These unstable and reactive dogs are also differentiated along an extraversion-introversion continuum: the choleric (unstable extravert) and the melancholic (unstable introvert) (see *Experimental Neurosis* in Volume 1, Chapter 9). Whereas adaptive types are preferentially sensitive to signals of reward (sanguine) or signals of avoidance (phlegmatic), reactive types are preferentially sensitive to loss of comfort (choleric) and loss of safety (melancholic). Finally, adaptive types shown an affinity for activating the seeking and social engagement systems, whereas reactive types show an affinity for activating the anger and fear emotional command systems.

Choleric (c-type) dogs may be particularly vulnerable to the adverse effects of environmental deprivation, excessive crate confinement, and a lack of daily training and play. Failure to provide c-type dogs (high sensitivity for frustration/low anger and attack thresholds) with appropriate daily stimulation and training conducive to organized and balanced attention and impulse control may rapidly elevate frustration levels while at the same time lowering aggression thresholds. C-type dogs may be susceptible to the sensitizing effects of restricted tactile stimulation and crate-related conflict in association with signals of loss and frustration. Such dogs may develop reactive elaborations in response to innocuous interference and loss of comfort while resting in favorite locations (see *Bonding with the Crate)*. C-type dogs may also show an increased susceptibility to separation-distress reactivity as the result of sensitization occurring in association crate-related conflict and frustration. The separation-reactive c-type dog may attack as the owner leaves the house. On the other hand, melancholic-type (m-type) dogs may be more vulnerable to environmental situations or change producing too much stimulation or arousal, perhaps gradually activating behaviors aimed a reducing it (e.g., compulsive licking). Whereas c-types may become increasing reactive in response to stimulation levels falling below homeostatic set points, m-types (high sensitivity for anxiety/low threshold for fear and escape) may be affected by intolerance for stimulation that exceeds homeostatic set points. As the result of restricted tactile stimulation and conflict produced in association with excessive crate confinement and anxiety, m-type dogs may be more prone to develop reactive aggressive elaborations in response to innocuous threat signals. M-type dogs may be particularly susceptible to separation reactivity occurring in association with anxiety. Dogs presenting with an admixture of c-type and m-type propensities (high sensitivity to frustration and anxiety combined with low anger and low fear thresholds) may be prone to panic-related aggression and separation-distress reactions. Both c-type and m-type dogs tend to *react* in response to environmental changes producing frustration and anxiety, whereas sanguine (s-type) and phlegmatic (p-type) dogs tend to *adapt* to environmental changes producing frustration and anxiety. However, under conditions of excessive crate confinement,

neglect (absence of training, exercise, and play), and environmental conditions lacking consistency and order, s-type and p-type dogs may become progressively unstable in the direction of c- and m-types.

The role of crate confinement in the etiology of behavior problems has not been scientifically established, but empirical impressions and logic dictate that it probably plays an important role in the development or exacerbation of many adjustment problems. In the absence of daily socialization and training, organized behavior may gradually degrade, causing a dog to lose its ability to respond competently to social signals. Even more significantly, however, under the influence of disorderly social circumstances, lacking sufficient predictability and controllability to elaborate viable prediction-control expectancies, the dog may be rendered particularly vulnerable to the stressful effects of excessive crate confinement and social isolation. Such dogs may fall victim to the disorganizing effects of inconsistent punishment and reward, causing them to become progressively incompetent and reactive to ambivalent social interaction. Given the organizing effects of learning on the development of competent attention and impulse control, it is reasonable hypothesize that a converse effect follows when dogs are exposed to excessive confinement and isolation (marginalization) in combination with disorderly or deranged social interaction—conditions that place dogs at the greatest risk of developing adjustment problems. In contrast, dogs that are integrated into a home-life situation consisting of orderly interactions are much less likely to experience an exacerbation of predisposing influences or develop an adjustment problem. Given the ubiquitous presence of crate confinement and its potential for producing stress, environmental and social deprivation, and abuse, it is odd that so little research is currently available with which to evaluate its potential role in the development of adjustment problems. Clearly, given the adverse behavioral and physiological effects associated with kenneling (Hubrecht et al., 1992; Clark et al., 1997; Coppinger and Zuccotti, 1999) and evidence of an increased risk of relinquishment in situations where dogs spend most of the day in a crate (Patronek, 1996), sufficient grounds exist to justify a serious examination of the potential role of crate confinement in the etiology of behavior problems (see *Deprivation and Trauma* in Volume 2, Chapter 2). Hopefully, in the future, researchers performing relevant cynopraxic studies will routinely collect such data to help flesh out the roles of excessive confinement and social-interaction deficiencies in the development of adjustment problems.

Freedom Reflex, Loss of Control, and Restraint

Healthy dogs are endowed with a robust freedom reflex, and they accept crate confinement and other forms of restraint (e.g., halter control) begrudgingly, frequently only after a significant struggle. As such, crate confinement is not only a condition of restraint, it also represents a loss of control. The loss of control over significant events is a necessary condition for producing experimental neurosis; however, the critical factor for producing neurotic disturbances is restraint (see *Liddell: The Cornell Experiments* in Volume 1, Chapter 9). Under conditions of restraint, exposure to inescapable aversive stimulation exerts pronounced behavioral and cognitive disturbances (see *Learned Helplessness* in Volume 1, Chapter 9). The condition of crate confinement satisfies both of the requirements for inducing neurotic elaborations. The chronic inhibition of the canine freedom reflex by daily crating is probably a source of significant conflict and stress for dogs and, when occurring in combination with a social environment lacking consistency and controllability, a convergence of potent behavior-disorganizing influences may be unleashed. If exposed to crate confinement without counterconditioning, dogs and puppies often protest vigorously with distress vocalizations and persistent efforts to escape, such as scratching and biting at the cage walls. The dog's initial resistance and resentment slowly yield and, after a variable period of diminishing effort, the dog may slip into a state of depressed resignation. The dog's ability to accept such restraint may not occur without a significant risk of harm, how-

ever. In postpubertal and adult dogs, the sorts of behavior prompting owners to crate their dogs often arises from a failure to establish consistent communication and control efforts, thereby only compounding difficulties, making things much worse, and postponing the proper resolution of the problem.

Ethological Rationalizations of Crate Confinement

A common rationalization for crate confinement is based on a questionable assumption that the dog is a denning animal, naturally prepared and well adapted for life in a crate. Despite the widespread circulation of this belief, there exists little factual evidence to support it. The belief that the dog is a denning animal is flawed in several ways, as Borchelt (1984) points out:

> The average dog book refers to dogs as "den dwelling" animals and presumes that confining imparts a feeling of security to a puppy. Dogs, in fact, are not den dwelling animals, although in a variety of canids the dam will construct a nest (often underground) for the pups. The nest is a defense against predators and protection against inclement weather. The pups use it as a "home base" from which they explore, investigate and play. There is no door on the den which encloses the pups for many hours. In many cases, "crate training" a puppy will attenuate vocalization and elimination, and prevent chewing. Unfortunately, it may also exacerbate these behaviours and sometimes leads to psychosomatic signs or hyperactivity elicited by the owner's return … Crating or other confinement (e.g., isolating in a small room) is highly likely to exacerbate a separation problem once it has occurred for any length of time, or for a puppy with a previous attachment and separation problem. (171–172)

Although wolves do prepare dens to whelp and rear their young, they do not use such places as general sleeping or resting areas. In fact, as early as 10 to 12 weeks of age, wolf pups are generally moved from den locations to rendezvous sites ("open-air kindergartens") where they are left while adults go on hunting sorties (Young and Goodman, 1944/1964; Allen, 1979). Corbett (1995) has reported that dingoes exhibit similar den habits, moving pups from den sites at about 8 weeks of age to various rendezvous areas, usually rock ledges. Ironically, this is precisely the time when most domestic puppies are first introduced to their "four-sided" dens. Wolves normally make their beds under conifer trees or on rock outcroppings where they have an unobstructed view of the surrounding terrain (Murie, 1944/1987). After the pack has satisfied itself on a kill, they often expend a great deal of energy to find open areas to lie down and sleep (Mech, 1970):

> After feeding intensively, wolves then seek a suitable spot in which to rest and sleep. If the sun is shining and the wind is light, they prefer open areas such as ridge tops or expanses of ice, and they will travel several miles to get to such places. There they sprawl out on their sides or bellies for several hours. During windy, snowy weather, they curl up in protected areas such as beneath evergreen trees, where they remain for long periods. (190–191)

The preceding discussion is not intended to eschew crate confinement altogether or to persuade dog owners not to use crate confinement as a responsible training tool; it is intended, however, to balance the promotional propaganda of advocates recommending crate confinement as an unabashedly positive thing, a virtual utopian condition for the dog, satisfying the dog's "den instinct," and similar misunderstandings and exaggerations. Crate advocates routinely espouse crate confinement as a way of life for family dogs, without fully appreciating the harmful side effects that may occur as the result of excessive restriction and social isolation. The convenience of crate confinement and the social permission afforded by glib rationalizations has beguiled many dog owners into believing the myth wholesale. For people convinced that their dog loves its crate, keeping it confined for 16 to 18 hours a day in a laundry room is not such a bad thing: after all, the dog is a "den" animal. As a result, many dog owners have come to regard the crate as a panacea for controlling undesirable behavior. Instead of dedicating the necessary time and effort needed to socialize and train the dog properly, the crate has become a steel straightjacket for controlling untreated behavior problems.

Contrary to the popular hype, the crate is not a "home," nor is it a "den": it is a place of confinement. In essence, the crate mechanically suppresses a dog's behavior, restrains the dog's freedom of movement, and imposes a loss of control; as such, crate confinement is a condition of punishment (loss of reward) that can be highly aversive and stressful for a dog reactive to such restraint. Successful crate training requires gradual exposure and counterconditioning. Perhaps, in the future, a manufacturer will develop an inexpensive feeder and manipulandum that can be attached to the crate and interfaced with a program conducive to sustaining a dog's interest, thereby helping the dog to form a more positive association with the crate. Performing PFR training before crating a dog may help it to relax, especially if a well-conditioned olfactory-signature odor is left behind to maintain the effect. Introducing the crate slowly and making it comfortable with soft or tasty toys and objects scented with the owner's odor can help to reduce adverse side effects, but it will not eliminate them. In the case of dogs that require long-term crate confinement, appropriate compensatory stimulation and activities should be provided. The cynopraxic process is dedicated to nurturing and supporting the dog's capacity for freedom by means of training and play. As such, crate confinement is viewed as an aversive technique and used as any other aversive technique, that is, as a necessary evil toward a greater good (see *Cynopraxis and Ethics* in Chapter 10) (Table 2.4). The goal of crate training should be to get the dog out of the crate as soon as possible, and to use the crate as little as possible in the service of training and space-management objectives.

Table 2.4. Summary of adverse effects of excessive crate confinement

Excessive confinement may result in deleterious sensory and behavioral deprivation.
Social and environmental deprivation provides motivational setting events for hyperactive and intrusive social excesses.
Influences of confinement-related frustration may generalize over numerous behavior systems (e.g., social, appetitive, and exploratory).
Upon release from confinement, undesirable social behavior may be strongly reinforced and integrated into the dog's postconfinement repertoire.
Excessive confinement is stressful for a highly sociable and dependent family dog.
Improper crate training may exacerbate separation distress.
Four-sided confinement (a trap) is a natural condition of vulnerability and may activate survival mechanisms associated with biological adversity.
Excessive confinement interferes with normal training, adjustment, and adaptive functioning.
Excessive confinement may socially marginalize a dog within the family system.
Since the condition of confinement is inescapable, symptoms of learned helplessness may develop especially in the case of dogs experiencing a highly level of aversive arousal while confined to a crate.
Frantic efforts to escape from the crate may result in serious injuries to the dog or its death.
Repeatedly forcing a dog into a crate may cause it to become aggressively reactive at such times.

Fears and Phobias

PART 1: ORIENTATION AND BASIC CONCEPTS

Working with fears and phobias requires considerable insight and technical skill. First and foremost, cynopraxic counseling and training activities should cultivate owner understanding and management strategies, as well as introduce and demonstrate procedures aimed at gradually reducing a dog's fear and fear-related behavior. Many common fears can be successfully treated; however, some phobias are highly resistant or intractable and may show only limited improvement despite the most conscientious training efforts. In such cases, counseling efforts should emphasize management strategies designed to help an

owner cope with the challenges of living with a fearful dog.

COPING WITH FEAR

Keeping in mind that fear is primarily under the control of Pavlovian influences (Maren, 2001; see also *Classical Conditioning and Fear* in Volume 1, Chapter 6), it is unlikely that emotional responses associated with fear (e.g., trembling and panting) are significantly influenced by reward and punishment. Nonetheless, instrumental escape and avoidance efforts associated with fearful arousal may strongly influence fear-related behavior. The way fearful behavior is managed has a direct effect on fearful arousal and its perpetuation. For example, although vocal encouragement and petting can have a calming and beneficial effect on a moderately fearful dog, such comforting efforts may also inadvertently reinforce fear-related behavior by providing the dog with a shield of safety, behind which it can escape or avoid fearful situations. Although owner attitudes and anxiety do not appear to play a particularly prominent role in the etiology and maintenance of major phobias (see *Owner Mental States and Behavior Problems* in Volume 2, Chapter 10), an owner's apprehensions about a dog's behavior when approaching fear-eliciting objects or situations may significantly influence therapeutic outcomes. In such circumstances, the dog is not likely to attribute the owner's worry to *itself* or to its behavior, but will more likely interpret the owner's worry as something bearing on the developing situation, perhaps increasing its own wariness. By adopting a confident attitude, excessive worry and apprehension about a dog's behavior can be avoided. Helping the owner to establish basic control over the dog's behavior is one of the best ways to instill confidence. As the owner's control over the dog improves, he or she will naturally feel more secure and relaxed when confronting potentially disruptive situations with the dog. Similarly, dogs under control appear to be more secure and confident, seeming to equate the owner's enhanced control over them with a safer environment.

Obviously, effective behavior therapy and training entail that both the owner and the dog learn how to cope more effectively with fear. Dogs cope with aversive situations through a variety of cognitive, behavioral, and physiological means. Appreciating the interaction between fearful behaviors and underlying physiological changes is extremely important (see *Autonomic Nervous System-mediated Concomitants of Fear* in Volume 1, Chapter 3). High levels of stress associated with fearful arousal may interfere with adaptive behavior, resulting in persistent maladaptive coping strategies that impede the extinction of fear. Emotionally stressful situations appear to contribute to the development of phobias and their expression (Jacobs and Nadel, 1985). For example, dogs exhibiting separation anxiety appear to be more prone to develop storm-related fears, perhaps as the result of an increased vulnerability to fear-eliciting stimuli stemming from emotional stress. Similarly, separation anxiety may present comorbidly with thunder phobias, requiring that both problems be addressed together. Frank and colleagues (2000) have reported that 40% of dogs with thunder and noise phobias also exhibit concomitant symptoms of separation anxiety. The threshold-lowering effects of stress can also be observed in dogs fearful of strangers and unfamiliar dogs.

When confronted with aversive situations, dogs typically cope by engaging in activities that serve to reduce the danger:

- Escape from eliciting stimulus (flee)
- Displace the source of aversive stimulation (fight)
- Increase vigilance or searching behavior (flirt)
- Wait for the situation to change (freeze)
- Tolerate or accept the situation (forbear)

Constructive coping strategies involve behavioral efforts designed to render an unfamiliar or threatening environment more predictable and controllable. Many dogs are fearful of unfamiliar things and situations because they are uncertain about their ability to predict and control them, often operating under the influence of toxic expectancies or dysfunctional learning experiences. Such dogs may *expect to fail* when faced with difficult or threatening situations (adversity). Expecting to fail when confronted with unfamiliar or

adverse situations is a potent source of anxiety and frustration. Anxiety and frustration are the emotional corollaries of situations in which unfamiliarity or detrimental cognitive and learning influences undermine a dog's ability to predict and control critical events effectively (see *Anxiety* in Volume 2, Chapter 3). As an aversive or threatening situation proves unpredictable and uncontrollable, anxiety and frustration correspondingly increase and impede adaptive behavior, perhaps causing the dog to become progressively hyperreactive (choleric type) or hyporeactive (melancholic type). However, as the result of experiences in which a dog has learned that it can successfully control aversive situations and threats, it naturally acquires an enhanced sense of competency and confidence, learning to *expect to succeed* when faced with adversity (see *Efficacy Expectancies* in Volume 2, Chapter 3). Under the influence of positive efficacy expectancies, the dog is more likely to approach uncertain situations in a more confident, success-oriented, and adaptive way (sanguine and phlegmatic types). Cynopraxic behavior therapy consists of reward-based procedures aimed at reducing adverse behavioral stress (anxiety and frustration) while at the same time training the dog to cope more competently and confidently with uncertain and unfamiliar situations.

Basic Training and Fear

Many dogs exhibiting excessive fear or generalized anxiety appear to do so under the influence of a negative expectancy with respect to their ability to cope with aversive events effectively (see *Efficacy Expectancies* in Volume 2, Chapter 3). Threatening situations present significant prediction and control problems for fearful dogs. Following exposure to aversive events under highly controlled and predictable conditions, dogs appear to learn how to cope more competently with their presentation, showing less distress and physiological arousal than when such events occur uncontrollably or unpredictably (see *Fear and Peripheral Endocrine Arousal Systems*). As a dog's competency and confidence improves, it becomes progressively relaxed. Relaxation naturally competes with fear and anxiety, providing a significant counterconditioning influence over fearful arousal.

Competency, Confidence, and Relaxation

A chief objective in the management of fear is to promote an expectancy of success in dogs. Intensive reward-based basic training is a constructive starting point for developing such a positive attitude. The improved communication and cooperation attained by attention therapy and basic training provide numerous benefits for fearful dogs. A probable factor explaining this improvement is the high degree of consistency and order that such training affords. The enhanced control and prediction associated with basic training translate into increased competence, relaxation, and expectancies of comfort and safety. In addition to establishing instrumental control, various appetitive and ludic conditioned emotional responses are simultaneously formed between signals, responses, and outcomes that have been repeatedly linked and rewarded with affection, food, and play in the process of training. As the result of orderly and repetitious patterns of basic training, dogs learn to cope more competently and confidently with social and environmental pressures placed upon them. Basic training provides an island of order and safety that can help ground anxious and fearful dogs and provide a stable platform for graduated counterconditioning and response-prevention procedures. As standard expectancies are established, positive prediction error and dissonance effects can be used to further enhance training and therapy efforts.

The cynopraxic training process renders a dog's behavior more predictable and controllable; however, to the extent that it achieves such an effect, the dog is empowered with an enhanced ability to predict and control the trainer (see *Hitting and Missing the Mark* in Chapter 10). The combined emotional changes associated with reward and enhanced competence make the dog more receptive to approaching the surrounding environment in a correspondingly more confident and relaxed way, an extremely important transition in the management of fear. As the result of consistent and orderly reward-based training activities,

insecure dogs appear to learn gradually to respond to the wider social and physical environment as though it were organized by similar rules. As training proceeds and a dog's trust grows toward the owner and the surrounding environment, playful modal activities may be educed and integrated into the training process to further extend and generalize the dog's adjustment, making it more natural and durable. Play and relaxation are the emotional antipodes of fear and anxiety. Learning to play in situations previously evoking fear is facilitated by first bringing trained behavior under the control of play rewards, gradually linking the various signals, prompts, responses, and so forth, with ludic associations. Play and reward-based training mediate a potent comfort/safety bias that is incompatible with fearful inhibition, indecision, and vigilance. By means of gradually transferring training and play activities into feared or unfamiliar situations, more competent and confident coping behavior is organized and integrated, while incompatible appetitive, social, and ludic associations antagonize or abolish situational fear and anxiety.

Sit-Stay Training and Relaxation

Reward-based attention therapy and basic training involving sit-stay and down-stay conditioning is often performed in advance of counterconditioning and desensitization efforts. During such training, appetitive and social affects elicited by the presentation of rewards may be associatively linked with contextual cues, signals, and the rewarded response itself (V. L. Voith, personal communication, 2002). Attention therapy and basic training can be particularly useful in the case of counterconditioning procedures that require dogs to remain as relaxed as possible in one place while attenuated fear-eliciting stimuli are presented and antagonized by stronger incompatible stimuli. In addition to providing an emotionally conducive platform for the reduction of fear via counterconditioning, basic training enhances a dog's ability to control significant events competently, thereby promoting expectancies conducive to enhanced confidence, relaxation, and feelings of safety (see *Benefits of Cynopraxic Training* in Chapter 1).

Victoria Voith's Sit-Stay Program was developed with this objective in mind (see Appendix A). While working with David Tuber in the late 1960s and early 1970s in Ohio, Voith found that training dogs to sit and stay afforded several therapeutic benefits for the treatment of behavior problems (Voith, personal communication, 2002). Owners presenting dogs for behavior therapy were taught how to train them to sit and stay by using a reward-only training technique. The owner-trainers were explicitly instructed not to use a stern voice or forceful means and were urged to limit training to social and appetitive rewards only. Sit-stay training not only taught dogs to sit still but also appeared to teach them how to relax. She noticed after a week of sit-stay training that many of the problems exhibited appeared to improve without any other treatment and regardless of the type of problem presented. In addition, Voith noted that the bond between the dog and the owner had changed in positive ways. Several factors may have played a contributory role in mediating these rapid behavioral and relationship changes, but Voith speculates that two general influences were probably most important:

1. Less aversive interaction between the dog and the owner may have decreased the stress, anxiety, and frustration underlying the presenting problems.
2. Enhanced mutual attentiveness occurring in association with reward-based training may have produced significant changes of affect and mood incompatible with stress, anxiety, and frustration.

Voith also observed that many owners showed attitude changes that may have also contributed to a more positive response to treatment:

- They learned how dogs learn.
- They showed increased pride in their dog.
- They became more enthusiastic and committed to the therapy process.
- They showed an enhanced appreciation of the dog's intelligence and abilities.
- They seemed less distressed and more optimistic about the resolution of their dog's problem.

Voith subsequently composed an autotutorial sit-stay program that she gave clients as a handout. The program is included in Appendix A, with some modifications. The autotutorial organizes the training process into a progression of sit-stay skills of increasing duration, distance, and difficulty. In addition, during sit-stay training, performance criteria are presented in accordance with an errorless learning format, whereby dogs are prepared for each new requirement in advance, with the goal of minimizing stressful errors and maximizing efficient acquisition.

The emphasis placed on errorless learning and positive reinforcement in the sit-stay protocol raises a number of questions with respect to the differential effects and side effects of reward and punishment on emotional behavior and stress. At least one study raises a concern about potential adverse side effects associated with inhibitory stay training (Wilhelmj et al., 1953) (see *Liddell: The Cornell Experiments* in Volume 1, Chapter 9). The researchers found that it took several weeks to months of intensive inhibitory training to quiet dogs enough to get accurate basal blood pressure readings. As a result of such training, however, many dogs showed a potent hypertensive response as well as signs of exaggerated emotional reactivity toward trivial environmental changes (e.g., strangers and noises) and changes of routine. The amount of training given to the dogs appeared to affect the severity of the dog's response adversely:

> The degree of training seems to be of considerable importance in that highly trained and conditioned animals give much greater blood pressure responses to trivial changes in the experimental environment and procedures than animals that are less highly trained. (1953:394)

In addition to the duration of training, a dog's temperament strongly influenced how it responded to inhibitory training. Dogs with stable temperaments were relatively unaffected by intensive inhibitory training, whereas dogs exhibiting unstable and emotionally reactive temperaments were most harmfully affected by it—findings consistent with Pavlov's observations concerning the vulnerability of choleric-type and melancholic-type dogs to neurotic elaborations. On a side note, these findings underscore the importance of selecting dogs for practical training that are highly stable to begin with, since emotional reactivity and instability may not improve with training, but may in fact worsen over time under the influence of demanding inhibitory training. Highly monotonous and repetitive inhibitory training may be particularly damaging to emotionally reactive and unstable dogs as the result of overstraining inhibitory attentional and impulse-control mechanisms (see *Locus of Neurotogenesis* in Volume 1, Chapter 9). Further, these findings point to the possibility that certain forms of intensive sit-stay training and restraint may be problematic with respect to long-term behavior-therapy efforts aimed at reducing fear and enhancing a dog's tolerance for environmental stimulation. These undesirable effects may exert an especially pronounced deteriorative effect in emotionally reactive dogs, such as those with behavior problems in associated with anxiety, fear, and aggression. Unfortunately, the report does not contain a description of the procedures used to train dogs for blood-pressure testing, leaving significant questions up for debate concerning its relevance.

The sit-stay program designed by Voith has not been implicated in producing similar adverse side effects and probably does not risk doing so, but it remains to be rigorously tested and evaluated for both beneficial and adverse side effects. A major difference in the case of dogs trained in accordance with the sit-stay protocol is they are not compelled by restraint to stay; that is, they perform the response by virtue of self-imposed restraint—they want to sit and stay. The freedom of choice appears to exert a protective effect on the development of neurotic elaborations (Liddell, 1956). However, such freedom is not only a characteristic of food training but present in virtually all forms of standardized animal training:

> In the case of the seeing-eye dog or the performing seal in the circus the self-imposed restraint developed through training *enhances* their effective and skilled behavior. Although they perform at signal, they do so with zest. Spontaneity and initiative are not quelled. Such animals are not brow-beaten. Freedom of action after the work period remains unimpaired. (Liddell, 1956:35)

Without choices, a dog's adaptation to significant events may be thwarted, causing it to become rapidly inhibited or impulsively reactive. Provided that the dog can escape or avoid aversive events, a choice remains available to it, thereby minimizing adverse side effects. The most common and chronic obstruction to making choices effectively is a lack of order in the occurrence and controllability of significant training events and outcomes. Events lacking predictability and controllability are disabling to a dog essentially because they make effective choices impossible for it. The sit-stay protocol combines a freedom to choose in the context of highly predictable and controllable signals and outcomes—ideal conditions for appetitive learning.

Any behavioral procedure that is capable of producing a significant benefit should also be capable of producing adverse side effects, if used improperly. The notion that training with positive reinforcement only produces less stress and promotes beneficial emotional changes during inhibitory sit-stay training remains a hypothesis that is overdue for experimental evaluation and validation. Although the sit-stay program appears to be useful and generally beneficial, the placebo effect is a powerful and pervasive influence that can profoundly alter the perceived efficacy of behavioral procedures—an effect that can be excluded only by controlled experimentation and clinical trials. Given the widespread use of the sit-stay program in the treatment of behavior problems, it is critical that appropriate tests be carried out to confirm its efficacy in order to justify claims attributed to its use. The dramatic and in some cases almost miraculous effects anecdotally and clinically attributed to the protocol suggest that sit-stay training ought to produce a robust effect that distinguishes it from other ways of training dogs to sit and stay. The sit-stay program should also outperform procedures in which appetitive and social rewards are presented on a noncontingent basis.

A starting point for such research might be to obtain baseline behavioral and physiological indices (e.g., cortisol, blood pressure, and heart rate) and then to compare that data with measures taken at week 1, week 2, and so forth, thereby obtaining a tentative within-subject indication of stress-related behavioral changes occurring as the result of the implementation of reward-only training. In addition to short-term effects, follow-up data should be collected. Given evidence of change, additional experiments might be performed to test whether reward-only training was specifically the agent of change rather than other causes incidental to sit-stay training [e.g., increased positive attention (more petting and food rewards)], increased orderliness of interaction between the owner and the dog, or the discontinuation of aversive and provocative stimulation.

Many practitioners using the sit-stay protocol take for granted that reward-only training produces superior therapeutic effects, but does it? If it does, why does such a benefit occur? If the reward-only strategy is selected as the result of welfare or humane considerations, then that underlying intent should be made clear at the outset and not mixed with efficacy considerations, except insofar as they can be demonstrated. In other words, if the basis for using a reward-only strategy is a matter of enhanced efficacy and therapeutic outcome, then appropriate data should be provided in support of the rationale together with outcome assessments showing a superior effect. To address these issues, a series of experiments need to be performed to evaluate how sit-stay training with food and petting only, in accordance with the errorless format, performs in comparison with other methods of training that use different procedures and combine varying proportions of food, petting, manual restraint, mild leash prompting, and so forth. These comparisons should be based on established behavioral and physiological indicators of stress (e.g., cortisol and blood pressure) and emotional reactivity. For example, one experiment might involve training two groups of dogs yoked together under identical training conditions, except that one group is given intensive sit-stay conditioning in accordance with the errorless sit-stay protocol, while the other group receives an equal number of voice commands, bouts of petting, and treats, but randomly distributed over the training session on a noncontingent basis (i.e., the rewards and signals are unlinked to a sit or stay response). This sort of study could be

modified and performed as a clinical single-subject reversal design, whereby the effects of sit-stay training could be systematically compared with noncontingent reward or attention therapy without a sit or stay response (i.e., conditioning of an orienting, attending, or following response). For example, dogs could be divided into two groups, with one receiving 1 week of sit-stay training followed by 1 week of attention training, whereas the second group is reversed, with dogs receiving 1 week of attention training followed by 1 week of sit-stay training. In cases where a larger number of dogs are available, a randomized, placebo-controlled, reversal design could be used, thereby obtaining the added power of a group-statistical analysis.

Another set of experiments could be performed to compare the errorless and reward-only group with two experimental groups using varying amounts of rewards, prompting, and restraint together with a control group. In one of the experimental groups (restraint), dogs might be trained with manual restraint, voice commands and hand signals to sit and stay, with leash prompting in combination with contingent appetitive and social rewards presented to reinforce sitting and staying. A second restraint group might consist of dogs trained to sit and stay in a similar way, but with appetitive and social rewards presented on a randomized noncontingent basis in accordance with a yoking procedure, whereby the same rewards given to the reward-only group are also given to the restraint group, regardless of what they are doing at the time of a reward's delivery. Finally, dogs in the control group receive no sit-stay training but are also yoked to the reward-only group, thereby receiving an identical treatment in terms of signals and reward stimulation. Additional studies could be performed to evaluate and compare the reward-only sit-stay and down-stay procedures with other techniques of sit-stay training in order to assess its relative efficacy, practical viability for use in applied settings, and relative ability to provide a conducive platform for counterconditioning. Given the rather simple and straightforward nature of such behavior studies and the widespread use of the sit-stay protocol in the professional treatment of frequently serious and dangerous behavior problems, it is rather extraordinary that no significant studies exist to date that evaluate its rationale and claims of clinical efficacy.

Neurobiological Substrates of Anxiety and Fear

A major adverse influence affecting a dog's ability to cope with fear-eliciting stimuli is early sensitization of neural circuits mediating the fight-flight response (see *Stress and Flight or Fight Reactions* in Chapter 4). Emotional stressors affecting the mother during gestation, together with excessively stressful postnatal conditions, may exert a lifelong detrimental influence on the way dogs cope with fear- and anger-provoking situations (see *Maternal Separation and Stress* in Chapter 4). Together, heredity and adverse prenatal and postnatal stressors may destine many young dogs to express reactive traits and tendencies before they open their eyes, requiring that such dogs obtain early preventive treatment to improve their ability to develop an adaptive coping style and to minimize the long-term effects of stressful sensitization to the fight-flight system. Stress-sensitized dogs may show a lowered threshold to startle and fear, rapidly learn fear-eliciting associations, and show a deficient ability to extinguish fearful associations once they are established. Knowing how fear is processed, learned, stored, and extinguished at the neural level provides useful insight into how to prevent and treat it effectively.

Startle and Fear Circuits

Startling auditory events are processed by a direct pathway between the thalamus and amygdala and an indirect pathway between the thalamus, prefrontal cortex, hippocampus, and amygdala (Figure 3.1). The direct pathway between the thalamus and amygdala serves to reflexively orient dogs toward the source of stimulation and prepare them for emergency action, whereas cortical and hippocampal inputs provide more specific information about the eliciting stimulus and its contextual significance (LeDoux, 1996) (see *Neurobiology of Fear* in Volume 1, Chapter 3). Of significance to sound-related phobias, the

lateral amygdala contains neurons that are highly sensitive to acoustical stimulation. Some of these neurons are prone to rapid habituation and dishabituation, perhaps performing an important fear-related function by detecting novelty and change. Other groups of amygdala neurons are dedicated to loud noises, perhaps mediating unconditioned startle responses to threatening noises such as thunder (Bordi and LeDoux, 1992) (see *Habituating and Consistently Responsive Neurons* in Volume 1, Chapter 3). These various neurons may undergo modification as the result of learning, resulting in threshold and tuning changes that may make them selectively responsive to certain auditory stimuli and not others.

Afferent pathways from the auditory cortex and thalamus to the lateral amygdala use the excitatory neurotransmitter glutamate. Within the lateral amygdala, these glutamate tracts form synaptic connections with inhibitory GABAergic interneurons. GABA (gamma-aminobutyric acid) is known to play an important role in the modulation of fear and anxiety (see *Glutamate and GABA* in Volume 1, Chapter 3). GABA-mediated inhibition within the lateral amygdala is of tremendous interest with respect to noise-related events triggering fear. Excessive sensitivity to fear-eliciting stimuli may reflect a deficiency of GABAergic-related inhibition over glutamatergic neurons. The inhibitory modulation of glutamatergic networks generating fear and anxiety appears to be mediated by serotonin receptors expressed on GABAergic interneurons (Stutzmann and LeDoux, 1998). Serotonin (5-hydroxytryptamine or 5-HT) modu-

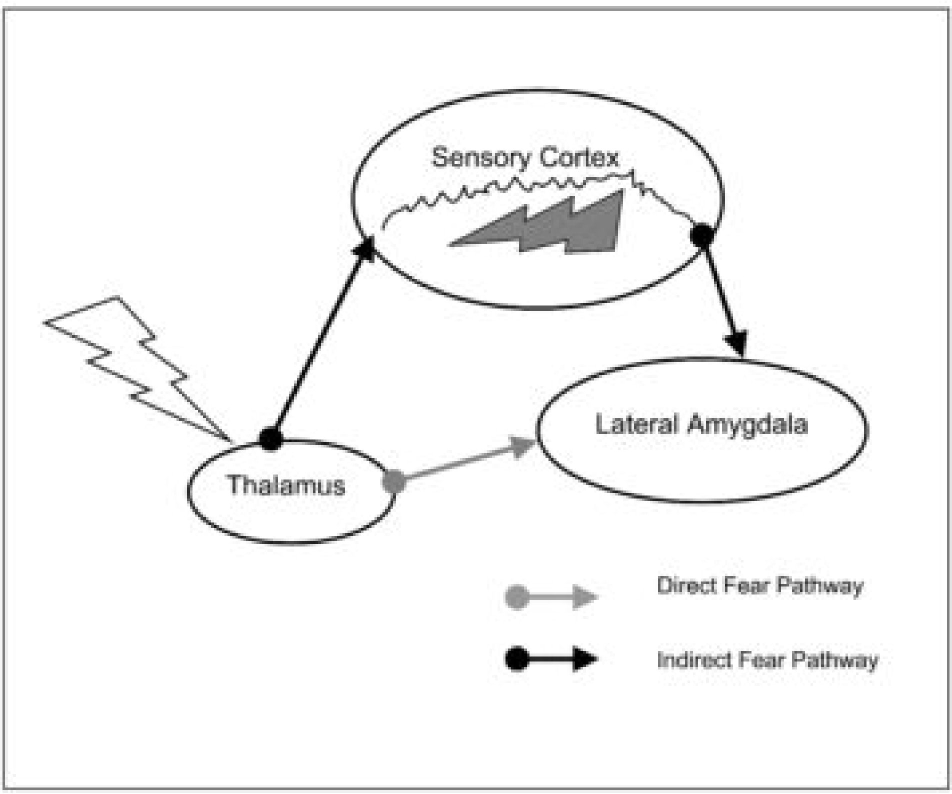

FIG. 3.1. Both direct (thalamo-amygdala pathway) and indirect (cortico-amygdala pathway) fear pathways converge on the amygdala. The direct pathway produces rapid orientation and preparation for emergency action, whereas the indirect pathway provides additional specific and contextual information about the eliciting stimulus.

lates anxiety via the 5-HT_{1A} receptor, the absence of which renders affected animals vulnerable to increased anxiety-related behavior (Hendricks et al., 2002). Medications targeting GABA and 5-HT activity are frequently used separately or together to treat refractory noise and thunder phobias (see *Pharmacological Control of Anxiety and Fear*). Fear-related glutamatergic activity is also modulated in the context of fear conditioning by gastrin-releasing peptide (GRP), a glutamatergic cotransmitter that binds to GRP-receptor sites located on GABAergic interneurons (Shumyatsky et al., 2002). GRP activates a GABAergic interneuron-mediated negative (inhibitory)-feedback effect on glutamatergic neurons. In addition to dampening fearful arousal, GRP, via this signaling network, appears to exert an amygdala-specific inhibitory effect on conditioned-fear learning. Genetically modified mice, not expressing GRP receptors, show an increased responsiveness to fear conditioning, enhanced long-term potentiation, and stronger long-term fear memory (Shumyatsky et al., 2002).

Circulating glucocorticoids also appear to play a prominent role in the serotonergic inhibition of cortical and thalamic sensory inputs to the amygdala. In fact, the inhibitory effects of serotonin appear to *depend* on the presence of glucocorticoids (corticosterone) (Stutzmann et al., 1998). The production of circulating glucocorticoids is under the regulatory control of the hypothalamic-pituitary-adrenal (HPA) axis. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to release glucocorticoids (cortisol and corticosterone). ACTH is released into the bloodstream by the pituitary in response to corticotropin-releasing factor (CRF)—a neural hormone secreted by the paraventricular nucleus (PVN) of the hypothalamus in response to stress. In addition to releasing ACTH, the pituitary gland releases ß-endorphin under CRF stimulation. Circulating adrenal glucocorticoids exert a restraining negative feedback effect on the hypothalamus, causing it to decrease CRF release, thus completing the HPA axis (see *Hypothalamus* in Volume 1, Chapter 3). Adrenal hormones also affect hypothalamic CRF output via opponent feedback effects exerted by the amygdala and hippocampus (LeDoux, 1996). Under the influence of glucocorticoids, the hippocampus restrains CRF, whereas the amygdala stimulates the PVN to produce more (see *Neural Stress Management System and Fear Conditioning* in Volume 1, Chapter 3).

In addition to initiating the chain of events leading to the secretion of glucocorticoids, CRF appears to coordinate a cascade of stress-related neural events that contribute to the expression of anxiety and fear. The CRF system projects to the locus coeruleus, where it exerts an excitatory influence on the production of norepinephrine (NE). Increased NE turnover is associated with increased emotional reactivity, hypervigilance, and disturbances of attention and concentration abilities (Valentino and Aston-Jones, 1995)—states consistent with clinical anxiety and fear. NE dysregulation has been clinically implicated in the development of various human anxiety disorders, posttraumatic stress disorder, and depression (Heim and Nemeroff, 1999). CRF and NE appear to interact within the central nucleus of the amygdala, with NE stimulating CRF release. Microinjections of CRF antagonists into the central amygdala significantly attenuate fear-related arousal and behavior (Koob, 1999). CRF also plays a focal regulatory role in the production and release of 5-HT. Kirby and colleagues (2000) found that CRF produces a dose-dependent, biphasic effect on 5-HT-producing neurons in dorsal raphe bodies. At high doses, perhaps, comparable to the CRF levels present during acute stress, CRF excites 5-HT-producing neurons. However, at low doses, perhaps, comparable to CRF levels associated with chronic stress, CRF exerts an inhibitory effect on 5-HT production. Price and colleagues (1998) have reported a similar biphasic effect of CRF on 5-HT activity. CRF microinjections in the striatum also affect 5-HT release in a dose-dependent manner. Again, they found that high doses of CRF increase extracellular 5-HT levels, whereas low doses decrease 5-HT levels. In both studies, the predominant effect of CRF on 5-HT activity was inhibitory. These findings suggest the possibility that acute stress associated with fear may initially increase 5-HT production and release, whereas chronic stress associated with anxiety

may gradually decrease 5-HT activity. A CRF-mediated increase in NE turnover together with a reduction in 5-HT activity may impede the brain's ability to modulate stressful sensory inputs effectively and regulate behavioral responses to it. NE and 5-HT dysregulation appears to play a functional role in a wide gamut of dog behavior disorders and problems (see *Neurobiology of Behavior and Learning* in Volume 1, Chapter 3). In addition to dysregulating NE and 5-HT activity, excessive stress appears to perturb prefrontal dopaminergic functions responsible for mediating refined adaptation, selective attention, and the control of emotional behavior (Arnsten, 1998). Dopamine imbalances have been implicated in a variety of stress-related psychiatric disorders (Pani et al., 2000) and animal behavior problems (Dodman and Shuster, 1998).

The localization of long-term memories produced by fear conditioning is a complex and controversial area of research. Several brain areas appear to play contributing roles, but the actual areas dedicated to fear memories have not been completely determined. Although Pavlovian fear conditioning appears to be localized in the amygdala and depends on long-term changes localized there (Rogan et al., 1997; Maren, 2001; Shumyatsky et al., 2002), memories are also formed in other parts of the brain providing complementary fear-related functions. For example, the contextual information and motor habits associated with the expression of fear appear to be stored in the hippocampus and striatum, respectively (LeDoux, 2000). Whereas the amygdala plays a significant role in the consolidation of memories associated with inhibitory avoidance conditioning (Wilensky et al., 2000), it does not appear to modulate or inhibit (e.g., extinguish) conditioned-fear responses once they have been established. Conditioned fear originating in the amygdala is dependent on inhibitory influences originating outside of the amygdala, especially the prefrontal cortex (LeDoux, 1996). Finally, conditioned fear and anxiety appear to result from neuronal long-term potentiation (LTP) mediated by glutamate. LTP produces excitatory presynaptic changes in cortical and thalamic neurons that, in turn, exert enduring effects on postsynaptic electrical activity in the amygdala (Tsvetkov et al., 2002). GRP appears to exert an inhibitory effect over LTP and the formation of long-term fear memories (Shumyatsky, 2002).

Once established, emotional fear memories are highly durable and may be permanent, but their expression can be restrained by extinction memories formed in the prefrontal cortex (Milad and Quirk, 2002). Training activity that successfully mediates extinction may do so by converting operative fear-related establishing operations into fear-restraining abolishing operations, whereby subcortical fear memories localized in the amygdala and thereabouts are actively inhibited and prevented from triggering fearful arousal and escape/avoidance behavior in response to the conditioned-fear stimulus. Along with revised prediction-control expectancies developed in the context of graded interactive exposure and other cynopraxic behavior-therapy efforts, emotional establishing operations are calibrated to match fear-incompatible control incentives and goals, instrumental control modules, and adaptive modal strategies (*Basic Postulates, Units, Processes, and Mechanisms* in Chapter 10). These various cognitive and emotional regulatory changes mediated by behavior therapy are theorized to take place on a preconscious level, involving a complex neural network of interacting sensory, motor, emotional, and cognitive comparator loci, and positive- and negative-feedback systems located throughout the brain, which are coordinated by executive memories (i.e., prediction-control expectancies and establishing/abolishing operations) (see *Neural Comparator Systems* in Chapter 10).

The resolution of fear-related problems depends on the integrity of executive control functions to disconfirm fear-related expectancies and to activate relevant abolishing operations as well as to consolidate new expectancies and establishing operations incompatible with fear. Fears stemming from precognitive stages of development or resulting from sensitization may dodge executive control due to the absence of prediction-control functional expectancies and establishing operations. The executive control of fear appears to depend on

the formation of prefrontal linkages with subcortical fear circuits operating at the time in which the fear memories are formed. Fears acquired independently of executive control appear to evade executive modulation until adequate prediction-control expectancies and calibrated emotional establishing operations are integrated to regulate fearful arousal to guide functional behavioral adjustments.

The interaction between the amygdala and the cortex is bidirectional, with the amygdala exerting a significant influence on the way that fear is processed at the cortical level. In addition to modulating cortical activity, the activation of subcortical arousal systems by the amygdala indirectly affects the quality of cortical functioning (LeDoux, 2000). As a result of this close interaction, executive control systems localized in the prefrontal cortex may be adversely affected by chronic fear and persistent anxiety. Executive control systems process expectancies and contextual information associated with fear-eliciting situations, playing a major role in the way dogs respond to fear and, most importantly with respect to behavior therapy, the way in which they respond to extinction and counterconditioning efforts (see *Extinction of Conditioned Fear* in Volume 1, Chapter 3). Under the influence of chronic fear and stress, executive functions localized in the prefrontal cortex may become disturbed and hinder the dog's ability to cope effectively with conditioned fear, as well as interfere with its extinction (see *Stress-related Influences on Cortical Functions* in Volume 1, Chapter 3). In addition, the accumulated effects of acute and chronic stress may make dogs more sensitive and reactive to fear-eliciting stimulation, emphasizing the importance of early intervention. As dogs age, some may become more susceptible to noise and thunder phobias, perhaps reflecting an age-related biological degeneration of critical brain areas dedicated to the modulation of conditioned fearful arousal (see *Hippocampal and Higher Cortical Influences* in Volume 1, Chapter 3).

Fear and Peripheral Endocrine Arousal Systems

Peripheral cortisol appears to provide an objective measure of stress in dogs (Beerda et al., 1998), especially when combined with relevant behavioral changes indicative of stress. Individual differences clearly exist with respect to the way animals cope and recover from stressful experience, with some showing a rapid recovery and others recovering more slowly (García and Armario, 2001). Putatively, the ideal pattern is robust glucocorticoid release followed by rapid recovery. Stress-prone animals exhibit impaired HPA-axis recovery, with increased levels of circulating glucocorticoid hormones present long after the termination of aversive exposure. Interestingly, nervous and normal pointer dogs do not appear to exhibit significant differences with respect to HPA activity (Klein et al., 1990), a finding that appears to conflict with earlier anatomic work that found that nervous dogs had larger (hypertrophied) adrenal glands (see *Nervous Pointers* in Volume 1, Chapter 5). Nervous pointers were found to be more prone to develop severe mange, suggesting the possibility of stress-related immunosuppression. In addition, nervous pointers are typically smaller than normal counterparts, exhibiting significantly lower plasma levels of insulin-like growth factor, suggesting that chronic stress associated with fear may affect the hypothalamic-growth hormone axis (Uhde et al., 1992).

As the result of Pavlovian conditioning, adrenal glucocorticoid release can be modulated (increased or decreased) by conditioned stimuli and contextual cues paired with appetitive and aversive stimulation (Stanton and Levine, 1988). A conditioned stimulus paired with aversive stimulation tends to increase glucocorticoid output, whereas a conditioned stimulus paired with an attractive appetitive or social stimulus tends to decrease glucocorticoid output and appears to stimulate the release of oxytocin and other neuropeptides conducive to the mobilization of an antistress response (see *Origin of Reactive versus Adaptive Coping Styles* in Chapter 4). Instrumental learning also appears to have a significant effect on adrenal glucocorticoid activity and blood pressure. Dogs exposed to uncontrollable aversive events exhibit a significant increase of cortisol output in comparison to dogs that are able to escape stimulation (Dess et al., 1983). Likewise, the signaled loss of

control in the context of instrumental avoidance training causes a pronounced increase in cortisol output (Houser and Paré, 1974). In addition to HPA-activity changes, the loss of instrumental control produces a significant elevation in blood pressure. Gaebelein and colleagues (1977) found that the blood pressure of dogs remained unchanged during signaled avoidance conditioning, but increased significantly when they were exposed to unsignaled avoidance conditioning. In general, dogs show a strong ability to cope and to adapt to stressful situations, as revealed by a steady decrease in cortisol output over time (Hennessy et al., 1997) and ability to adapt under suboptimal conditions (Campbell et al., 1988). Kuhn and colleagues (1991) found that both cortisol and corticosterone levels where significantly increased in dogs during transportation, but rapidly returned to baseline levels overnight once the destination was reached.

Under the activating influence of fear, various emotional, behavioral, and physiological adjustments are rapidly recruited for emergency action. Many of the coordinated responses associated with learned fear and acute fearful arousal, including startle, freezing, and fight-flight behavior, are orchestrated by the central amygdala (Van de Kar and Blair, 1999) (Figure 3.2). As previously discussed, the central amygdala also exerts a positive (excitatory) feedback effect on the release of CRF by the hypothalamus. In addition to triggering HPA-axis activity, the hypothalamus supports emergency emotional and behavioral adjustments occasioned by fear by mediating conducive physiological changes. In concert with the brainstem (medulla) and spinal preganglionic neurons, the hypothalamus activates the sympathetic division of the autonomic nervous system (ANS). Sympathetic autonomic activation produces global bodily changes in preparation for emergency action, including the secretion of epinephrine (adrenaline) by the adrenal medulla. Epinephrine complements and sustains various fear-related bodily changes set into movement by direct sympathetic arousal, including increased heart and respiratory rates and skeletal-muscle tonus and readiness for action. Epinephrine also appears to play a significant role in the learning of fear (McGaugh, 1990; Costa-Miserachs et al., 1994) and the extinction of fear (Richardson et al., 1988). Signs of fear, such as panting and pupillary dilation, are under the control of the sympathetic division of the ANS (see *Hypothalamus* in Volume 1, Chapter 3). Sympathetic activation is followed by parasympathetic deactivation, resulting in a return to homeostatic balance. Parasympathetic opponent or rebound effects are commonly seen subsequent to fearful arousal, increased salivation, pupillary constriction, bradycardia, and loss of bladder control.

PHARMACOLOGICAL CONTROL OF ANXIETY AND FEAR

Hart and Hart (1985) have described the benzodiazepine diazepam as the drug of choice for the management of a variety of fear conditions. A significant advantage of diazepam is its rapid assimilation and attainment of therapeutically effective levels. Cohen (1981) reported that diazepam attained peak levels of effectiveness in the dog within 30 minutes. A major drawback, however, is that diazepam is very rapidly metabolized and cleared from a dog's bloodstream in a manner that far exceeds the metabolism rates observed in humans. To maintain therapeutic concentrations, dogs may require three doses per day (Löscher and Frey, 1981). Other benzodiazepines (e.g., clorazepate and alprazolam) have become more popular, in part, because they are much longer acting—a significant advantage in the treatment of fear-related problems. Benzodiazepines are not usually recommended for fearful dogs exhibiting comorbid aggression, because they tend to exert a disinhibitory effect on the fight/flight system and may lower aggression thresholds (Woolpy and Ginsburg, 1967; Marder, 1991; Dodman and Arrington, 2000). Finally, diazepam is prone to produce pronounced ataxia in dogs, including unsteady coordination and falling down, side effects that many dog owners find unacceptable. Ataxia may be particularly problematic in excitable dogs, because they may injure themselves while attempting to escape a fearful situation. With respect to diazepam's effect on escape behav-

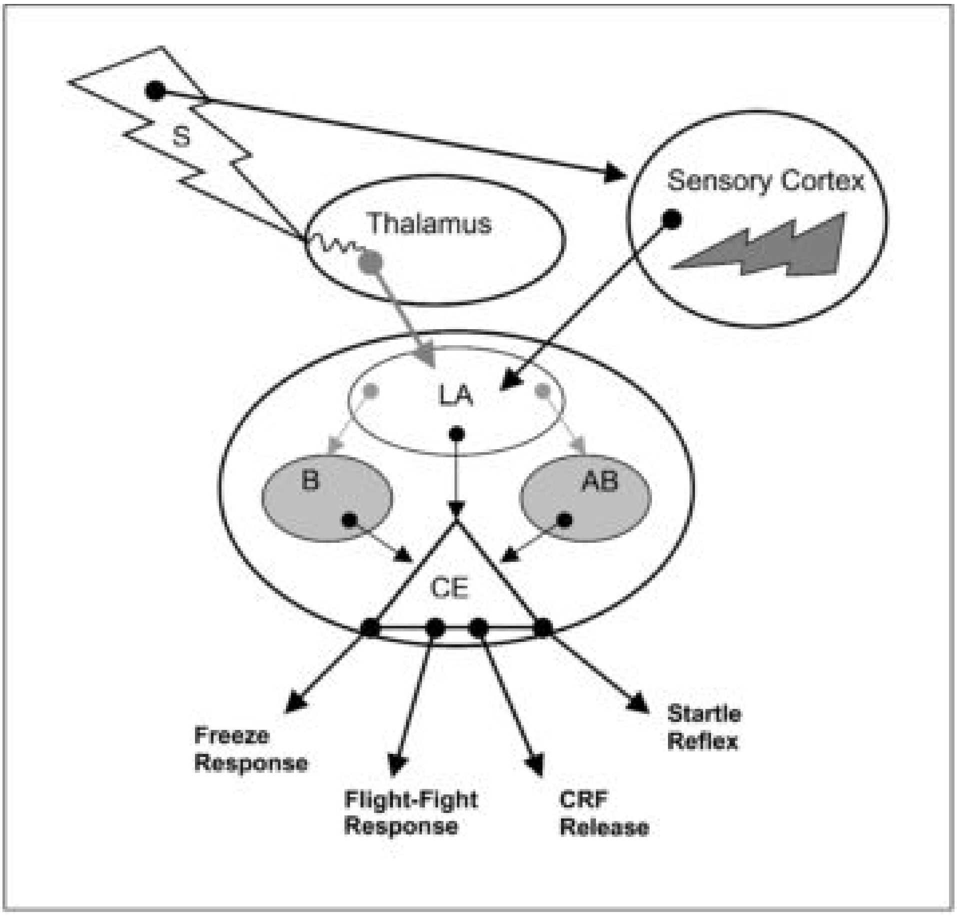

FIG. 3.2. The amygdala orchestrates the expression of a number of emotional and behavioral responses to fear via various neural connections, including the startle reflex (reticulopontis caudalis), freeze response (central gray), CRF release (paraventricular hypothalamus), and flight-fight responses. AB, accessory basal nucleus; B, basal nucleus; CE, central nucleus; CRF, corticotropin-releasing factor; and LA, lateral nucleus. After Ledoux (1996).

ior, Cohen (1981) found that it, in comparison to other drugs tested (haloperidol, chlorpromazine, thioridazine, and clozapine), exhibited a minimum effectiveness for inhibiting escape behavior at dosages not also producing pronounced ataxia.

Desensitization effects produced under the influence of benzodiazepines may be state dependent, with improvements lasting only so long as the dog is under the influence of medication. The transfer of beneficial desensitization and counterconditioning effects may be facilitated by gradually tapering off the medication (Swonger and Constantine, 1983). Although tapering may help in some cases, a number of reports indicate that tapering procedures may not work in the case of highly fearful animals. For example, Woolpy and Ginsburg (1967) performed a series of experiments with various anxiolytic drugs (e.g., librium, chlorpromazine, and reserpine) in an effort to help socialize human-avoidant wolves. Although tranquilization had pronounced effects on social approach behavior, compressing into 4 days what took several months to achieve without medication, the

therapeutic benefits were short lived and fully disappeared after the drugs were withdrawn:

> Thus far we have not been able to bring any animal to the fully socialized stage under drug or to maintain it at the most positive approach stage achieved under drug after the drug has been withdrawn, regardless of the variations in the tapering-off process. (362)

They also found that tranquilized wolves tended to be more aggressive and failed to offer typical threat displays, making them more dangerous to handle (disinhibition). Tranquilized wolves also did not exhibit the tail wagging, mouthing, and other social expressions shown by well-socialized counterparts. Similarly, in the case of nervous Catahoula and pointer dogs, benzodiazepines (e.g., diazepam, chlordiazepoxide, and oxazepam) facilitated the acquisition and performance of a simple instrumental bar-press task, but when the medication was discontinued the bar-press behavior was lost (Murphree, 1974). Neither gradual nor rapid discontinuation of medication had a significant effect on transferability of the bar-press task from the drugged state to the nondrugged state. Puppies receiving chlorpromazine for several weeks (weeks 8 to 15) after being socially isolated from weeks 3 to 7 showed little or no lasting social or psychological effects, even though medicated puppies appeared to extinguish trained avoidance responses more rapidly than unmedicated controls (Fuller et al., 1960). Yet, in the case of puppies exposed to longer periods of isolation (weeks 4 to 15), chlorpromazine appeared to exert a highly beneficial and lasting effect (Fuller and Clark, 1966). The researchers found that chlorpromazine in combination with handling significantly reduced the emotional arousal and behavioral disorganization (emergence stress) associated with environmental and social exposure after long-term isolation, indicating that such drug treatment, when combined with forced social contact (response prevention), might totally eliminate the postisolation syndrome in puppies expressing a "robust genotype" (Fuller and Clark, 1966:257) [see *Environmental Adaptation (3 to 16 Weeks)* in Volume 1, Chapter 2].

The experimental treatment of genetically influenced canine behavior disorders with tricyclic antidepressants has produced mixed results. Iorio and colleagues (1983) have described a strain of beagles exhibiting global behavioral disturbances. Among other things, these dogs exhibited deficits in their ability to form social attachments, appeared withdrawn and depressed (stooped posture, reduced activity, decreased alertness), and showed avoidance and failure to look at or make eye contact with human observers. Both imipramine and amitriptyline produced an improvement in 50% of the dogs after a 2-week delay, whereas benzodiazepines produced more immediate beneficial results. Dogs medicated with tricyclic antidepressants maintained improvement over the 24 hours between doses. After the medication was withdrawn, the abnormal behavior rapidly returned to pretreatment baseline levels (Iorio et al., 1983). Imipramine given daily for 4 weeks to nervous pointer dogs was ineffective against the social avoidance and fearful behavior exhibited by these dogs (Tancer et al., 1990). Chronic stress in association with fear and phobias appears to induce adverse neurobiological changes and dysregulatory influences over numerous neurotransmitter systems. Because 5-HT produces widespread neuromodulatory effects over subsystems relevant to the control of fear and the management of stress, serotonergic medications are frequently used in psychiatry to orchestrate far-reaching neurobiological changes to ameliorate depression and several anxiety-related disorders exhibited by human patients (Vaswani et al., 2003). Selective serotonin-reuptake inhibitors (SSRIs) and tricyclic antidepressants are also often prescribed by veterinary behaviorists in an effort to enhance 5-HT activity and to improve neural functions relevant to the reduction of anxiety and fear. These medications target serotonergic neurons, causing them to inhibit the reuptake of 5-HT from the synaptic cleft.

Currently, the most common medications used to treat anxiety and fear are clomipramine and fluoxetine, alone or in combination with a variety of benzodiazepines. Stein and colleagues (1994) have reported that clomipramine may be useful in

the treatment of fear-related problems in dogs. All of the dogs treated were unresponsive to behavior therapy alone or in combination with anxiolytic medications (diazepam and clorazepate) or a tricyclic antidepressant lacking potent 5-HT-reuptake inhibitory effects (amitriptyline). Clomipramine proved effective in all of the dogs treated (N = 5), with three showing improvement during the first week and additional treatment benefits accruing over time. Veterinary treatment protocols combining 5-HT-enhancing medications, such as clomipramine, together with long-lasting benzodiazepines (alprazolam) appear to be effective in treating thunderstorm phobias (Crowell-Davis et al., 2001). The efficacy of this combined approach to control pathological fears (e.g., thunder phobias) may be the result of a synergistic effect produced by SSRIs and benzodiazepines on the GABAergic modulation of glutamate afferent acoustical inputs projecting to the lateral amygdala. In addition, SSRIs probably mediate a modulatory effect over central amygdala efferent tracts by way of a serotonergic mechanism. Also, experimental evidence suggests that alprazolam may exert part of its anti-anxiety effect by decreasing CRF activity in the locus coeruleus, a brain site where CRF stimulates NE production (Arborelius et al., 1999)—a neurotransmitter believed to play a prominent role in the expression of anxiety and fear. Melatonin and amitriptyline have been used in combination to treat one case involving intense and generalized fearful arousal occurring in response to various noises, including such diverse auditory stimuli as birdsong and thunder (Aronson, 1999). The combination was reported effective for delivering a rapid reduction in noise-related fear. The positive therapeutic response was subsequently maintained by treating the dog with melatonin alone, which proved effective for controlling noise-related fears, including the fear of thunder occurring over subsequent seasons of storm activity. Aronson suggests that the rapid onset of fear reduction and the ability of melatonin to maintain the effect in the absence of amitriptyline make it likely that melatonin played a prominent role in mediating the effect. Dodman (1999) has also reported some success using melatonin to control noise-related fear (see *Pharmacological Control of Separation Distress* in Chapter 4).

Numerous physiological processes, including odor-conditioned histamine release in guinea pigs (Russell et al., 1984), odor-conditioned insulin release in rats (Woods et al., 1977), taste-conditioned immunomodulation (Ader and Cohen, 1985), and conditioned modulation of adrenal glucocorticoid release (Stanton and Levine, 1988), are influenced by classical conditioning. The sensitivity of physiological and endocrine functions to conditioning suggests the possibility that the effects of certain medications used to control fear could be harnessed or potentiated by means of Pavlovian conditioning. Many of the anxiolytic drugs prescribed to control fear exhibit rather rapid onset, producing global emotional and behavioral effects incompatible with fear. Usually such medications are given to dogs without consideration for contextual cuing and other potential conditioning effects. Perhaps by explicitly pairing a novel olfactory stimulus with medication a conditioned association between the odor and context could be established with the tranquilizing effects of the medication (Otto and Giardino, 2001). After repeated trials, the presentation of the odor alone might elicit some of the tranquilizing effects of the medication. Similarly, after repeated dosing in a certain location (e.g., a crate), a dog may learn to accept confinement there more readily.

Note: The foregoing information is provided for educational purposes only. If considering the use of medications to control or manage a behavior problem, the reader should consult with a veterinarian familiar with the use of drugs for such purposes in order to obtain diagnostic criteria, specific dosages, and medical advice concerning potential adverse side effects and interactions with other drugs.

EXERCISE AND DIET

A program of daily exercise is highly recommended for fearful dogs. Daily exercise appears to help balance neurotransmitter activity and restore efficient functioning of the brain's stress-management system (see *Exercise and the Neuroeconomy of Stress* in

Volume 1, Chapter 3). Rueter and Jacobs (1996) have reported that behavioral activity, especially rhythmic activities (e.g., walking, running, and swimming), exert a significant effect on 5-HT levels in various parts of the forebrain associated with fear conditioning, including the hippocampus, striatum, amygdala, and prefrontal cortex. The benefit of daily and long-term exercise is a heightened sense of well-being and an improved ability to cope with stressful arousal. Family dogs typically receive woefully inadequate routine exercise and may obtain significant benefits from walking, jogging, energetic play activities, and the like. Exercise activities should include taking the dog to unfamiliar places as is appropriate and safe. Another important basic consideration in the management of chronically stressed dogs is diet. Fearful dogs should be fed a high-quality, balanced diet. Hennessy (2001) found that giving shelter dogs an enhanced diet containing highly digestible protein and fat, produced a beneficial effect on HPA activity and behavioral responses to stressful situations, an effect that was augmented by brief periods of daily human contact and petting. Some evidence suggests that the manipulation of dietary protein and carbohydrate proportions (low protein/high carbohydrate) may increase the availability of tryptophan for 5-HT biosynthesis, perhaps helping to modulate certain fear-related problems associated with a 5-HT deficiency (see *Diet and the Enhancement of Serotonin Production* in Volume 1, Chapter 3). Dogs under the influence of chronic fear and stress may benefit from dietary supplementation with fish oils containing omega-3 fatty acids (Freeman, 2000). Foods enriched with the antioxidants vitamin E and alpha-lipoic acid (found in spinach) may ameliorate fear-related cognitive impairments associated with chronic stress and aging in some dogs (Packer et al. 1997; Milgram et al., 2002). Supplementation with soy protein offers another potentially useful, although currently unproven, dietary change that may exert a modulatory influence on anxiety. Soy meal contains estrogen-mimicking phytoestrogens. Phytoestrogens exert a number of behavioral and physiological effects, including the ability to bind selectively with and modulate estrogen receptors. When evaluated in an elevated maze test, rats fed soy diets rich in phytoestrogens showed a marked reduction of anxiety in comparison to rats fed a diet low in phytoestrogens (Lund and Lephart, 2001). Diets rich in soy phytoestrogens have also been shown to enhance learning and memory significantly in both animals and people (File et al., 2001; Lephart et al., 2002). The value of soy-rich diets for the management of fear and anxiety in dogs has not yet been evaluated, but the accumulating experimental evidence warrants appropriate investigation and trials for potential clinical efficacy.

A variety of herbal supplements have been found to exert anti-anxiety effects in animals and people (see *Herbal Preparations* in Chapter 4). Passionflower (*Passiflora incarnata*) may have some value in the treatment of certain anxiety disorders. Various parts of the passionflower have been shown to exert an anxiolytic effect comparable to diazepam in mice (Dhawan et al., 2001). A randomized, double-blinded, and placebo-controlled trial found that passionflower extract performed comparably with oxazepam in the treatment of generalized anxiety in human patients (Akhondzadeh et al., 2001). Another potential herbal remedy for managing anxiety in dogs that should receive future attention with respect to efficacy and safety is kava kava (*Piper methysticum*) extract. Kava kava has been demonstrated to be efficacious as an anti-anxiety agent in several double-blinded and placebo-controlled trials to reduce anxiety in people (Pittler and Ernst, 2000). Finally, a valerian-lemon balm combination has been shown to provide a soporific effect and an improved quality of sleep in human patients (Cerny and Schmid, 1999). The combination was well tolerated and produced minimal side effects. Perhaps such a combination might offer a useful benefit for the management of certain anxiety and fear-related problems or provide a mild sedative effect to encourage sleeping in restless dogs.

Numerous anecdotes and testimonials have attributed a calming and emotion-stabilizing effect to flower-essence remedies. One veterinary author has described potent physiological effects observed as the result of administering flower essences, even the man-

agement of bleeding during surgery: "If bleeding occurs during surgery, the Trauma formula, given every 30 seconds until the situation is resolved, can be very useful" (Blake, 1998:581). The value of flower remedies for the modification of emotional or physiological states has not been scientifically demonstrated in animals. With respect to anti-anxiety effects in people, two double-blinded, randomized, and placebo-controlled studies have been performed to evaluate the effect of various combinations of flower essences to control test-taking anxiety in students (Armstrong and Ernst, 2001; Walach et al., 2001). Neither study showed any benefit, above placebo, attributable to combinations of flower remedies for the control of test-taking anxiety.

Note: Since herbal and dietary changes may produce adverse side effects if not properly dosed or balanced, such manipulations aimed at producing behavioral changes should be carried under the advisement and guidance a veterinarian.

Active and Passive Contingency Management Strategies

The etiology and expression of fear-related behavior problems are influenced by interacting contingencies of classical and instrumental conditioning. An important aspect of the behavioral control of fear is to identify and manage these influential contingencies systematically, with the goals of reducing undesirable fearful behavior while at the same time increasing a dog's competence and confidence in the presence of fear-eliciting stimuli. Contingency management can be roughly characterized as a process in which relevant eliciting stimuli, responses, and response-produced consequences are carefully identified and then systematically manipulated to attain specific behavioral objectives. Behavioral output can be managed by both active and passive contingency management techniques. Active contingency management (ACM) refers to the collection of methods used to reliably produce overt and emotional behaviors incompatible with fear. These procedures include a wide gamut of common behavior modification and therapy procedures. In addition to actively manipulating associative and consequent contingencies, fear-related problems are passively managed by controlling a dog's contact with and immediate response to fear-evoking situations. Passive contingency management (PCM) refers to procedures that serve two complementary functions: (1) decrease uncontrolled exposure to evocative situations and (2) prevent or block evoked behavior by various means, including direct restraint and confinement. For example, in the first case, owners are instructed to avoid activities and situations that have evoked fearful behavior in the past, at least until appropriate procedures are in place to minimize fear and to help reduce its future expression. In the second case, procedures are introduced to block fearful avoidance and escape behavior. There are significant interactions between active and passive contingency management procedures, with most behavior-therapy techniques incorporating both active and passive components.

Habituation, Sensitization, and Preventive-exposure Training

Habituation and sensitization exert significant influences on the expression of fearful behavior (see *Habituation and Sensitization* in Volume 1, Chapter 6). Under ordinary circumstances, habituation and sensitization interact to adjust reflexive emotional behavior adaptively to environmental stimulation. Although mild fears can be attenuated by repeated exposure to a fear-eliciting stimulus or situation, pathological fears and phobias may resist habituation efforts or worsen as the result of repeated exposure. Habituation occurs when some response is repeatedly elicited—nothing more is needed than repeated stimulation. During habituation, the threshold, magnitude, and latency of the elicited response are gradually altered. For example, dogs fearful of traffic sounds may slowly learn to ignore such noises if given measured and systematic exposure to such stimulation. If, however, a dog, which has been fully habituated to traffic sounds, is frightened by a startling event, such as an accident or nearby exhaust backfire, the

previously habituated fear response may reappear or be dishabituated as the result of sensitization. Following the sensitizing event, the dog may become more reactive to traffic sounds than before and respond aversively to sounds that it had previously ignored.

Although habituation results in relatively stable changes in behavior or potential, the habituated response is subject to the influence of spontaneous recovery. Spontaneous recovery occurs when the eliciting stimulus is discontinued and presented again after some test period, at which point the habituated response may rapidly recover strength. In addition, habituation is highly sensitive to contextual influences and various concurrent stimuli that may serve either to facilitate or to impede habituation (Leibrecht and Askew, 1980). Repeated presentation of weak stimuli results in more rapid habituation than strong startling ones. For example, fearful responses to loud thunder may persist despite repeated exposure to the sound of thunder and may actually increase in magnitude with repeated exposure. Instead of habituating to the thunder stimulus, dogs fearful of thunder may become progressively reactive to it. If the sound of thunder is presented in a weaker form (e.g., a low-volume recording) the dog may rapidly habituate to the sound, but if exposed to loud thunder it will immediately dishabituate and exhibit the previously habituated fear response. Desensitization by habituation involves exposing dogs to graduated fear-eliciting stimuli without the presence of a counterconditioning stimulus, a process that can be rendered more effective by introducing various training and play activities at every stage to enhance confident interaction with the feared situation.

Habituation is an important aspect of puppy training. The goal of habituation is to provide a puppy with guided experiences to familiarize it with common sources of stimulation that it will likely encounter as an adult. As the result of habituation, puppies learn to respond to such stimulation without becoming overly reactive or panicky, but perhaps more importantly such preexposure helps to prevent conditioned fears from forming as the result of subsequent aversive or fear-eliciting exposure. Early habituation and preventive-exposure training (PET) appear to help immunize dogs against fear conditioning when exposed to startling or threatening stimulation involving similar stimuli or circumstances in the future. The habituation process is basically a latent-learning process in which repeated exposure to some situation or stimulus without consequence retards or inhibits the ability of the stimulus to form conditioned associations with threatening events later on (see *Latent Inhibition* in Volume 1, Chapter 6). Latent inhibition can play a particularly useful role in the prevention of fears acquired as the result of associative learning (Lubow, 1998). Uneventful preexposure exerts a robust effect that can be easily integrated into puppy-rearing practices. For example, a fear of being inside a car can be prevented by allowing the puppy to explore it on several occasions before going on its first car ride. The first few rides should be brief and end in playful or uneventful activities. Repeated and uneventful visits to the veterinary clinic can help reduce the risk of the puppy developing conditioned fears when aversive procedures (e.g., injections) are performed. Also, repeatedly exposing the puppy to grooming tools (comb, brush, nail clipper, and so forth) before using them to perform grooming chores may produce valuable latent-inhibition effects, interfering with fearful learning occurring in association with actual grooming. PET is particularly useful in the case of noisy devices (e.g., dremel and electric shears), which may require graduated exposure and counterconditioning to prevent an unconditioned fear. Puppies exhibiting noise sensitivities, especially when belonging to a family line with a predisposition to thunder phobias, should be given PET and preventive graduated counterconditioning using storm and thunder tapes to help prepare them for their first exposure to such fear-evoking stimulation. Without the immunizing effects of PET, the first exposure to thunder and lightning may trigger an enduring sensitization and fear. Thunder phobias may be easier to prevent than cure once they are fully established. Perhaps in areas where thunderstorms are common PET should be performed as a routine procedure in conjunction with other puppy-training and socialization efforts.

Although habituation may help modulate fearful arousal and aversive conditioning, inappropriate exposure to aversive situations may result in sensitization and adverse socialization effects that dispose affected dogs to overreact to social and environmental stimulation in adulthood. In addition to habituation, socialization helps to adjust a puppy's emotional response to social encounters with people and other animals. Early experiences with varied social stimuli serve to modulate fearful arousal when a puppy makes contact with people and other dogs. Puppies deprived of adequate habituation and socialization may develop pronounced deficits in their ability to interact normally with the physical and social environment, including the development of debilitating fears as adult dogs. In addition to increased sensitivity to fear conditioning between weeks 8 to 10, later developmental periods (e.g., 4 to 5 months of age) may occasion an increased responsiveness to fear-eliciting and territorial stimuli (see Serpell and Jagoe, 1995).

Social Facilitation and Modeling

Dogs exhibit a wide variety of social signals and displays in an effort to influence the behavior of other dogs and people. These signals typically produce an emotional effect in the receiver, functioning as an establishing operation conducive to the desired behavioral change. In addition to affecting the emotional state of the recipient, the emotional state of the sender of signals is affected. For example, appeasement displays appear simultaneously to evoke emotions incompatible with overt attack in the receiver while stimulating emotions compatible with submission in the sender. Some signals appear to be exhibited with the intention of reducing aversive arousal without signifying appeasement (see *Cutoff Signals* in Volume 1, Chapter 10). These cutoff or "take it easy" signals promote compromise and serve to quiet fearful or aggressive arousal. Dogs also exhibit a variety of displays intended to increase social arousal and affection (e.g., greeting rituals and play solicitation). Not only do dogs behave in specific ways to alter the emotional arousal of others, they are also highly responsive to the emotional behavior of others. Contagious behavior and social facilitation are common among dogs. For example, in a kennel situation, if one dog begins to bark in response to a strange noise near its run, other dogs in a remote part of the kennel will also bark, even though they had not heard the noise themselves.

The ability of dogs to be affected by the emotional states of others offers a potentially useful means for modulating certain forms of fearful arousal. Unfortunately, however, contagious behavior exhibits a significant degree of biological preparedness, with some emotional states and activities being more contagious than others. For example, dogs living in the same household may respond to storm activity in distinctly different ways. One of the dogs may become extremely fearful with the approach of a storm, while another may simple curl up and ignore it. A third dog may become alarmed by the sound of thunder and bark but not show evidence of fear. These differential responses to the approaching storm reflect different coping styles—styles of behavior that appear to be highly resistant to local social influences and contagion. Similarly, two dogs living together may exhibit very pronounced differences with regard to their respective responses to separation. Whereas one of the dogs may exhibit intense separation distress, the other may simply lie down and wait for the owner's return. Interestingly, the separation-reactive dog is often oblivious to the presence of the nonreactive dog; similarly, the separation-relaxed dog is not likely to become reactive as the result of social facilitation or contagion.

The relative resistance of intense fear to modulation by incompatible social contagion makes procedures designed to aid fearful dogs with jocundity and jollity seem somewhat questionable with respect to efficacy and treatment value. The author's attempts to induce emotional playfulness in highly fearful dogs by laughing and so forth have not been successful. In the presence of intense conditioned or unconditioned fear,

dogs appear confused or simply ignore laughter and other contrived efforts at jollity, and any benefit is rapidly overshadowed by growing fear. Feigned jollity may be too weak as a counterconditioning stimulus to support the effective and sustained modulation of fearful arousal. Nevertheless, in the case of mild fears associated with the introduction of new things or places or intense fears that have been reduced by other means, vocal jocundity and encouragement, together with various play activities, appear to provide useful diversions to help reduce fear (see *Play and Fear* in Volume 1, Chapter 3). For example, play can effectively promote familiarity and improved competency toward some feared activities (e.g., training dogs to swim or jump). Also, despite the aforementioned concerns regarding the efficacy of jollity as a counterconditioning stimulus, some fears may be modulated by presenting the dog with a prized toy or ball or by engaging the fearful dog in some activity that generally evokes excitement incompatible with fear, as indicated by the presence of tail wagging (Campbell, 1992). Perhaps better effects than obtained by feigned jollity may be attained by mimicking canine play signals, including play postures and sounds. Simonet and colleagues (2001) have reported that recordings of play-soliciting vocalizations (rapid huffing sounds) appear to increase the readiness of young dogs to play (see *Play and Leadership* in Chapter 6). Finally, although laughing and humoring fearful dogs may not significantly or reliably compete with fearful arousal, such vocalizing activities may help owners of such dogs to feel better by reducing their own anxiety, making such techniques useful placebos if not efficacious treatment modalities, especially in the case of owners showing high anxiety levels in response to the dog's fearful behavior. Reducing owner anxiety levels is not insignificant, since the owner's emotional state appears to affect how he or she copes with the dog's fearful behavior. Anxious owners appear to view their dogs' anxiety as more troubling or disturbing than do nonanxious owners (O'Farrell, 1997).

Some pathological fears and generalized anxiety disorders may respond beneficially to social facilitation and modeling. For example, McBryde and Murphree (1974) observed that social facilitation and modeling aided nervous pointers to become good hunting dogs. While hunting in the company of normal pointers, human-avoidant pointers became much more tolerant of human contact. Unfortunately, the beneficial effect did not endure after the dogs were returned to the laboratory. Similarly, Baum (1969) reported that the efficacy of response prevention for extinguishing fearful behavior in rats is greatly enhanced by the presence of nearby nonfearful rats. In the case of dogs living together in groups, socially fearful dogs appear to be emotionally supported by the activity of more confident dogs. Dogs that would otherwise avoid people are often much more willing to make such contact if in the presence of a people-friendly canine companion. This evidence suggests that the extinction of certain fears (especially those involving fear of people), counterconditioning, and the acquisition of prosocial behavior may be facilitated by the use of a more confident dog to model the desired behavior. In fact, dogs that are socially confident and outgoing can be very helpful as therapy assistants. The more outgoing dog provides a model of successful social behavior for the more socially inhibited one. For example, doling out treats to a confident canine cotherapist for approaching and staying near the trainer may help to lure an avoidant dog into closer proximity to obtain a share of the easy food. Seeing another dog eat may increase appetite in the fearful dog sufficient to overshadow or restrain its fear momentarily, thereby enabling it to make progressively closer and more relaxed contact with people. The model/rival procedure may possess value for momentarily altering mood or mediating rapid, but temporary, adjustments that may be subsequently strengthened and made more durable by reward training. Preliminary experiments appear to indicate that the model/rival procedure produces rapid changes in social and object-oriented behavior, perhaps having applications in the control and management of certain social and object-related fears (see *Complex Social Behavior and Model/Rival Learning* in Chapter 10).

Coping with Fear and Stress: Licking and Yawning

Voith and Borchelt (1996) have observed that licking and yawning often occur in situations involving conflict and stress. Dogs that are uneasy or fearful of approach often exhibit licking and lick-intention movements. They have also observed that yawning appears to occur in conflict situations involving a delay of gratification or frustration (e.g., waiting to be let outdoors). Licking activity may become an exaggerated or compulsive self-directed behavior, sometimes resulting in lesions to the legs (see *Licking, Sucking, and Kneading* in Volume 1, Chapter 5). They report that when a dog is restrained and exposed to an uneventful social situation in which it feels uneasy or fearful, it may involuntarily doze while sitting, standing, or lying down (sternal recumbency). Such dogs appear to fight an urge to doze that develops over time in the situation, finally losing muscle tone and slipping briefly into sleep, whereupon they start and awaken to continue the vigil. Such dogs appear conflicted between a need to maintain alertness and an opposing urge to fall asleep.

Yawning is common in similar situations of declining attention requiring an increased level of arousal and alertness. Dogs may yawn when forced to practice repetitive and monotonous training exercises, such as repeated sit-stay behaviors. In some of these dogs, yawning appears to present with penile erections, but it is not clear whether the erections are causally linked with the act of yawning or simply part of a coping response to such situations. Whether such dogs are stressed, bored, drowsy, or all three is debatable, but trainers can avoid such tedium by keeping their training sessions brief, reward dense, and playful. Yawning probably performs a cognitive-enhancement function by boosting ebbing attention under conditions in which the dog must continue to wait or defer. Similarly, yawning may help to mediate adjustments in response to unsettling social situations requiring that the dog maintain alertness while at the same time remaining inconspicuous and inactive. Yawning may also occur under certain fear-eliciting social situations. For example, Beerda and colleagues (1998) reported that yawning and stress-related oral activities (e.g., licking movements) occurred in association with fear produced by restraint or startle, but only if a person was present. These findings suggest that at least some stress-related yawning and licking may be expressed with a social intent (appeasement signal) that might not occur (or occur less frequently) in the absence of an appropriate social object. In addition, licking may perform a displacement or cut-off function, perhaps used to appease or pacify the approaching person or dog (see *Cut-off Signals* in Volume 1, Chapter 10). A pacifying function has been attributed to canine yawning, including a host of other sociosexual communication functions (Abrantes, 1997) and a controversial calming or reassuring effect that is purportedly induced when an owner yawns at a distressed dog (Rugass, 1997).

In humans, yawning is partially involuntary, socially contagious, and appears to increase alertness and arousal (Baenninger et al., 1996). Once yawning begins, it is often repeated and may facilitate yawning by others nearby, suggesting the possibility that it exerts a remote contagion effect via observation; however, merely thinking about yawning can also evoke the response. Although an increase in oxygen/carbon-dioxide exchange in the lungs has been proposed, the actual physiological function of yawning has not yet been determined. Yawning is phylogenetically ancient and is under the control of a variety of neurotransmitter systems and interactions, including stress-sensitive acetylcholine and dopamine pathways. Circulating glucocorticoids and other neuropeptides (e.g., ACTH and prolactin) exert a facilitative effect on yawning consistent with a stress-related function. Dopamine (D) appears to play a prominent role in the stress-related evocation of yawning via the release of oxytocin at the level of the paraventricular nucleus of the hypothalamus (see *Startle and Fear Circuits*), which subsequently activates an oxytocinergic pathway projecting to the hippocampus (Argiolas and Melis, 1998)—a potentially significant link-

age mediating the social contagion effects of yawning.

The multifaceted role of central oxytocin in the expression of sexual behavior (perhaps explaining the occurrence of stress-related penile erections), social recognition, attachment and bonding, and the diminution of irritability and aggression (Panksepp, 1998), suggests that yawning may help to modulate aversive emotional arousal produced in association with stressful social interaction (see *Neuropeptides and Social Behavior* in Chapter 4). Among olive baboons, anxious yawning and other self-directed behaviors (e.g., touching, scratching, grooming, and shaking) increase approximately 40% if the closest group member (within 5 meters) is dominant, which suggests that such anxious behavior may sometimes possess a social significance (Castles et al., 1999). Yawning may increase attention in social transitions requiring inactivity and deference, while at the same time helping to reduce social anxiety and aggressive arousal by producing incompatible cognitive and emotional changes via the release of oxytocin (e.g., enhanced social recognition) and other neural changes conducive to peaceful social transactions. Dogs can be trained to yawn by means of instrumental techniques (Konorski, 1967), which suggests the possibility that the response might be influenced by learning and used in some instances as a deliberate signal to indicate a readiness for increased activity, waning patience, or other information. Many dogs exhibit yawns that include drawn-out high-pitched squeaking or abbreviated high-pitched howl–like sounds that conclude with chomping or clacking sounds with a sigh of apparent exasperation. Such variations in canine yawning may be produced with a signaling intent, depending on the situational and motivational context in which they occur. Audible squeaks, chomps or clacks, and sighs may be used to draw the owner's attention to the yawn and to help clarify its significance, perhaps resulting in its periodic reinforcement.

Licking and lick-intention movements serve a significant canine social communication function when performed in the context of appeasement and care-seeking situations, but it is not clear whether licking actions performed by a person toward a fearful or stressed dog serve to produce a calming or reassuring effect or any effect at all. In the case of yawning, given its complex neurobiological nature and close association with the central release of oxytocin, one might best keep an open mind with regard to its potential value as a social signal and capacity for inducing a calming or pacifying effect. Casual experiments by the author to test the calming-signal hypothesis (i.e., the belief that yawning or licking might produce a calming effect in dogs) were without consistent effect, but some dogs do respond to human licking by licking back in return, by averting their gaze or head, by backing away, or by yawning in response to repeated licking actions, which raises the possibility that such signals might actually produce a mildly aversive effect in recipient dogs. Further, merely attracting the dog's attention repeatedly (Grahm et al., 1966) or petting it (Kostarczyk and Fonberg, 1982; Hennessy et al., 1998) may produce a calming effect of variable strength. As a result, some caution should be exercised in suggesting that such signals have special calming properties, particularly when used arbitrarily and out of context.

COUNTERCONDITIONING

Dogs experiencing fear may be functionally incapable of responding in an organized and purposive way to threatening situations. Extreme fear impedes purposive action, paralyzing the animal when it most needs to act effectively and decisively. Until the debilitating fear affecting these dogs is reduced to manageable levels, they will continue to react impulsively rather than learn how to cope in a more measured and adaptive way. The level of fear in such cases is not simply the result of some triggering event, but also reflects a dog's relative confidence and ability to exercise appropriate instrumental control over the threatening situation. To the extent that the dog is unable to control the situation, its fear may escalate into panic rendering behavioral efforts progressively disorganized and unadaptive. Under the influence of intense fear, and unable to respond in an organized way,

incompetent fearful dogs may cope by relying on primitive species-specific defensive reactions. Ultimately, the goal of behavior therapy is to improve a dog's behavioral coping skills when encountering aversive situations. However, the first step toward improved behavior is the initiation of efforts designed to reduce aversive arousal to a more manageable level (see *Counterconditioning* in Chapter 7).

Most common procedures used to control excessive fear in dogs involve some element of counterconditioning (Hothersall and Tuber, 1979; Voith and Borchelt, 1985; Shull-Selcer and Stagg, 1991). Graduated counterconditioning is performed by exposing the dog to a gradual progression of increasingly feared stimuli while simultaneously evoking emotional arousal incompatible with fear (see *Counterconditioning* in Volume 1, Chapter 6). Attractive and aversive stimuli exert mutually antagonistic behavioral, emotional, and physiological effects (see Dickinson and Pearce, 1977). An aversive stimulus can be gradually cross-associated with a hedonically opposite and incompatible emotional state by means of classical conditioning. In the presence of a fear-eliciting stimulus, relaxing or appetitive activities may inhibit or overshadow fearful arousal normally produced by the stimulus, allowing it to acquire attractive significance. Another way to conceive of counterconditioning is in terms of the reduction in escape and avoidance behavior. By repeatedly presenting the fear-eliciting stimulus while emotional responses incompatible with escape and avoidance are arranged to prevail and remain unperturbed by the aversive event (e.g., appetitive arousal), the previously feared stimulus may gradually become an associative signal for emotional responses incompatible with fear. Although counterconditioning may result in the development of new associations, the permanent uncoupling of the conditioned fear stimulus does not appear to occur as the result of the procedure.

As a result of counterconditioning, the aversive stimulus is classically cross-associated with reward incentives and pleasurable hedonic emotions that are antagonistic to fear. While fear elicits escape and avoidance, reward incentives stimulate approach, making counterconditioning prone to produce approach-avoidance conflict. Approach-avoidance conflict may be reduced by gradual exposure to a fear-evoking stimulus through small steps moving from least aversive to most aversive, until finally the dog can tolerate close contact with the feared stimulus or situation without experiencing disruptive fear. Under conditions of reduced fear, the dog can be encouraged to interact with the feared stimulus or situation more competently and confidently. The introduction of appropriate play-facilitated behavior and interactive skills is highly conducive at this point for the promotion of confident control expectancies and more natural social or exploratory modal behavior. Counterconditioning is likely to exert the most benefit in the case of fears resulting from socialization and habituation deficits or developing as the result of sensitization. Fear associated with conditioned escape and avoidance appears to be less sensitive to counterconditioning efforts.

Daily counterconditioning efforts should be recorded in a behavioral journal or chart (Figure 3.3). Methods such as interactive exposure with response prevention can be highly stressful for both dog and owner, and should be employed in combination with counterconditioning and positive-reinforcement techniques, perhaps helping to reduce adverse secondary stress and improving owner compliance. Finally, once a fear-evoking stimulus is reduced by exposure and counterconditioning, play therapy may be considered. Play is particularly useful for the acquisition of new prosocial behavior patterns or as a means to establish active interaction with a previously feared situation.

Fear Reduction and Approach-Avoidance Induction

Counterconditioning is used to alter an animal's fearfulness by associating the feared stimulus/situation with a motivationally antagonistic state. For example, dogs afraid of strangers can be encouraged to take food when people are nearby, thereby eliciting appetitive arousal incompatible with fear while in the presence of people. The attractive expectation of receiving food in the presence of nearby people motivationally competes

with fear otherwise triggered by their presence. After repeated trials, the approach of a stranger may gradually no longer just elicit fear, but instead cause the dog to eagerly anticipate the presentation of a tasty treat. Through gradual steps, the dog's fearful emotional arousal may be progressively offset with a new set of prediction expectancies, enabling the dog to interact less cautiously with strangers. Although such modifications and cross-associations may help to reduce certain aspects of the dog's response to the feared

stimulus and establish new positive associations, especially in the case of fears resulting from a lack of familiarity (habituation deficit) or as the result of sensitization, counterconditioning appears to be significantly less effective in the case of conditioned fears operating under the control of expectancies that have not been disconfirmed. Although counterconditioning may establish new associations that compete with the emotional responses elicited by the feared stimulus, it may not alter the subcortical fear memory. In effect, rather than resolving the conditioned fear, counterconditioning may result in establishing an approach-avoidance conflict toward the conditioned feared stimulus (see *Partial-extinction Effects, Response Prevention, and Behavioral Blocking*)—an effect that can be particularly problematic in the treatment of dogs presenting with aggression problems associated with fear and avoidance.

In addition to the use of graduated counterconditioning and other progressive exposure techniques, instrumental avoidance behavior may need to be blocked by appropriate means (Askew, 1996). This strategy is often necessary to convince a dog that its reactive avoidance behavior is unnecessary. Consequently, response prevention is a very important aspect of fear management and modification, since allowing a fearful dog to engage in escape/avoidance behavior during graduated exposure may result in an increase of fearful behavior rather than helping to decrease it. Dogs exhibit avoidance behavior to control fear-provoking situations, and since a dog is likely to achieve some degree of success and relief from such efforts, the behavior is likely to undergo reinforcement, that is, confirm the operative control expectancy. The potential for inadvertent reinforcement under such circumstances is significant. Escape and avoidance behavior prevents dogs from learning that the feared stimulus or situation is not really a threat. By gradually bringing a dog into a closer proximity with a feared situation, sometimes against its most vigorous resistance, it is able to learn that the stimulus or situation is harmless and, further, that such contact is actually associated with pleasant things. On the other hand, letting the dog bolt out of "harms" way is contrary to constructive training and counterconditioning efforts. Of course, it is important that a fearful dog be gradually desensitized to the trigger stimulus with an appropriate combination of fear-reducing techniques (e.g., habituation, counterconditioning, and stimulus change).

Critical Evaluations of Counterconditioning

Despite its widespread use and apparent efficacy in the treatment of human fear and phobias (Bellack and Hersen, 1977), over the years since Wolpe's discovery of systematic desensitization (Wolpe, 1958), scientific debate has questioned its efficacy for treating phobias. In particular, the need for antagonistic arousal and carefully constructed fear hierarchies has come under question and criticism (Marks, 1987). Neither the ranking of feared samples nor the presence of a relaxing/appetitive counterconditioning stimulus have proven especially significant with respect to the overall reduction of fear and anxiety, either in laboratory animals or in human patients exhibiting fearful behavior. Marks (1978a and b), who carried out an exhaustive survey of the relevant experimental and clinical literature, came to the following conclusion:

> Arousal level during exposure does not seem crucial for improvement, which proceeds at a similar rate whether patients are relaxed, neutral, or anxious during exposure. Controlled work shows both relaxation and deliberate anxiety evocation to be redundant, time-wasting, and unnecessary for the treatment of phobias and obsessions. Systematic reward has not been found especially helpful, though it assists motivation. … Exposure appears to be especially effective when it is interactional, with the patient actively approaching and grappling with the ES [evoking stimulus] in some way. (1978b:236)

He noted that working up the hierarchy of increasing fear arousal was just about as effective as working down in terms of final results.

Similar observations and concerns about the efficacy of graduated counterconditioning have been reported involving laboratory-animal subjects. For example, Delprato (1973) found that extinction following full

exposure to a fear-eliciting conditioned stimulus (fear-CS) outperformed both graded exposure and graded counterconditioning. In the protocol used in his experiments, counterconditioning with food actually impeded the extinction of fear. These findings suggest that food may serve only to divert an animal's attention away momentarily from a feared stimulus without significantly altering its fear. Further, the resultant distraction may cause animals to miss the significance of the conditioned stimulus, thereby shielding it from extinction. The failure of counterconditioning with food to reduce fear became apparent when the fear-CS was presented in the absence of food:

> Rather than facilitating elimination of avoidance, explicit pairing of the anxiety/avoidance competing response of eating with graded exposure to the aversive stimulus was equivalent to control treatment [no exposure to the aversive CS] and, relative to graded and nongraded exposure only, actually impeded elimination of the response. (53)

Delprato suggests that the effectiveness of graduated counterconditioning may be improved by presenting the fear-CS first and allowing the animal to recognize it fully as such before presenting food and other counterconditioning stimuli.

Lastly, upon reviewing a wide array of animal (and human) studies investigating fear-reducing techniques, Thyer and colleagues (1988) concluded that, although useful, counterconditioning appeared to be the least efficacious means for reducing fearful behavior. The most effective techniques, in order of decreasing value, were response prevention, response prevention with distraction, response prevention with noncontingent reward, and response prevention with contingent positive reinforcement (shaping). Despite some of the apparent procedural and efficacy problems with counterconditioning, the authors emphasized that both counterconditioning and positive reinforcement of behavior incompatible with avoidance have a useful place in the armamentarium of a comprehensive fear-therapy program. Oddly, given the rather problematic issues surrounding counterconditioning and the refractory nature of many fears (especially those associated with generalized anxiety and loud noises), it is rather astonishing that one author claims in a scientific journal to have a achieved a 100% success rate involving 89 fearful dogs by using a program of counterconditioning without drugs (Rogerson, 1997). Unfortunately, the study does not contain analyzable data or experimental controls with which to assess the validity of these dramatic and unexpected findings.

PLAY AND COUNTERCONDITIONING

The emotional excitement and joy produced by play are incompatible with fear, making play extremely useful for the treatment of mild to moderate social fears. If play can be produced in the presence of a fear-provoking stimulus, several potential benefits may be obtained. For one thing, play enhances a dog's confidence and willingness to take risks. Instead of the wariness, anxious vigilance, and inhibition associated with fear, play mediates a more curious, experimental, and spontaneous attitude toward the environment. Playful dogs are more free and able to behave in spontaneous ways, just because they are not overly preoccupied with the potential consequences of their behavior. Under the influence of play, fearful dogs may be more able to interact with the environment flexibly, thereby allowing them to learn and integrate new control modules, routines, and patterns under the active modal influence of play (see *Training and Play* in Chapter 1).

Trumler (1973) succinctly and correctly observed, "The dog learns by playing" (124). Playing is no less important in the case of normal skill learning than it is in the unlearning of fears. Activities associated with play and curiosity are unique in that they appear to be intrinsically reinforcing and apparently done for their own sake. The consummation of play appears to educe joy and immediate gratification. Play occurs without any apparent interest or concern for advantages in the future; the only goal of play is the perpetuation of play and the joy it produces. Play is a source of continuous reward for dogs, and behaviors used and integrated into play tend to become

progressively stable and reliable. While playing, dogs can safely practice and learn numerous social skills. Both play and curiosity appear to operate on a high level of cortical organization, driving a highly flexible and experimental attitude and behavioral interface with the environment, precisely the sort of thing that is needed by fearful and aggressive dogs to overcome their biased perceptions.

Not unexpectedly, fearful dogs are usually very inhibited and reticent to play while in the presence of the feared stimulus. This play inhibition is in sharp contrast to the animation that they may ordinarily exhibit when alone with owners in the safety of familiar surroundings. Fearful dogs are unable to respond to play invitations, not so much because they are unable to play, but simply because they do not *feel free* to play; that is, they are inhibited by fear. Encouraging dogs to play in a variety of situations with both familiar and unfamiliar partners helps to promote a more generalized prosocial attitude, gradually causing the dogs to view people less suspiciously—perhaps eventually causing the dogs to view people as potential playmates. Similarly, play can help to restrain arousal associated with environmental sources of fear such as loud noises; for example, Hothersall and Tuber (1979) reported that the noise-phobic Labrador retriever "Major" could better tolerate evoking stimulation if engaged in ball play (see *Major: A Thunder-phobic Dog* in Volume 2, Chapter 3).

Several dynamics govern play behavior, making it a fitting tool for this purpose. Play is influenced by a safe-expectancy bias and can be helpful to facilitate socially risky behavior in dogs. Such features of the activity are obviously very desirable in the context of interactive exposure. The safe expectancy associated with play is the outcome of natural or species-typical boundaries and rules regulating such contact and activity, permitting interaction that might be perceived as threatening under other circumstances. As a result, play allows individuals to become more intimately familiar with one another, it promotes affectionate bonding, and it helps to establish social stratification without the risk of inciting serious combative contests. In short, play facilitates the development of a friendly and joyful relationship (see *Fair Play, Emergent Social Codes, and Cynopraxis* in Chapter 10).

Instrumental Control and Fear

There is some inconsistent usage of the term *counterconditioning* in the applied and veterinary behavior literature. Counterconditioning, a classical conditioning procedure, is often used to describe instrumental training efforts in which an incompatible response to fear is prompted and positively reinforced. This mixed usage is somewhat problematic and should be avoided. Instrumental control efforts typically involve obedience commands (e.g., "Sit"), prompts, and consequences that may or may not provide secondary counterconditioning benefits. Separating fearful behavior into instrumental and classical fractions is somewhat arbitrary, but the division is useful in this case since not all instrumental control efforts necessarily exert a counterconditioning effect (e.g., behavioral blocking), at least not initially. In combination with response prevention and graded counterconditioning efforts, fearful dogs are often trained to perform various obedience modules and routines incompatible with escape and avoidance. Usually, dogs undergoing counterconditioning are given intensive preliminary training to enhance attention control and to perform a variety of basic exercises (e.g., a rapid and reliable sit and down response, indoor and backyard recall, starting exercise, controlled-leash walking, and a reliable sit- and down-stay lasting for at least a full minute under distracting circumstances). When exposed to the fear-provoking situation, these various instrumental behaviors are prompted through commands and various other signals to bring the dog into closer interactive proximity with the feared situation. The social and tangible positive reinforcers used to support exposure and interaction with the evoking stimulus may perform a significant counterconditioning function. Conditioned reinforcers appear to play an important role in this regard (see *Classical Conditioning, Prediction, and Reward* in Chapter 1). When properly conditioned, bridging signals acquire potent alerting and

orienting features that can be used to shape behavior incompatible with fear while at the same time eliciting antagonistic emotional arousal associated with reward. Brief and crisp vocal and mechanical sounds appear to be more effective as conditioned reinforcers than drawn-out vocal phrases. Maximal arousal of conditioned reward effects occurs with the onset of the conditioned reinforcer rather than its offset. A highly conditioned bridge can be used to introduce powerful positive prediction error and dissonance effects.

Stimulus Dimensions Influencing Fearful Arousal

The desensitization hierarchy is constructed by organizing the presentation of fear-provoking stimuli and situations along a continuum of increasing fearfulness. Several overlapping dimensions are involved, each of which should be given careful consideration when devising a hierarchy of graded exposure and desensitization. They include proximity, context, similarity, intensity (quantity), contrast (quality), duration, frequency, predictability, controllability, and stimulus continuity (Table 3.1). Desensitization can occur by counterconditioning (requiring the elicitation of incompatible emotional arousal) or habituation (repeated presentation of graduated samples of the fear-eliciting stimulus). Desensitization by habituation does not depend on the presence of a counterconditioning stimulus.

Counterconditioning Stimuli

When desensitizing fearful reactions by counterconditioning, a list of counterconditioning stimuli should be identified. A counterconditioning stimulus must be both incompatible with the feared stimulus and sufficiently strong to compete with its fear-eliciting properties (Figure 3.4). Counterconditioning stimuli usually have a calming, appetitive, or pleasurable effect on dogs. The most commonly used counterconditioning stimulus is food. A dog's relative interest in food is a sensitive measure of its emotional state, with anxious, fearful, or aggressive dogs often refusing food offered to them. Appetite and fear appear to inhibit each other reciprocally. Seeding the situation with treats that the dog can search for and easily find appears to work better as a counterconditioning stimulus than simply feeding it by hand as it stands or sits in the presence of the fear-eliciting stimulus. Searching activity appears to help restrain fearful behavior. Also, highly motivating appetitive stimuli varied in size and type will produce a stronger effect than giving the dog a food item of low reward value and novelty (e.g., kibble). Feeding the dog a highly appetizing meal in the presence of a graduated fearful stimulus can be an effective means to reduce fear reactivity, especially if it is done over several days or weeks.

Appetitive arousal and fear typically exert a pronounced antagonistic influence over each other in dogs, perhaps stemming from a close evolutionary affinity and organization at the level of the hypothalamus controlling approach and avoidance behaviors. Counterconditioning with food probably exerts an influence at the level of the ANS, wherein food-induced parasympathetic arousal works to avert or restrain fear-related sympathetic arousal (see *Hypothalamus* in Volume 1, Chapter 3). Appetite and fear are motivationally antagonistic to each other or, as has Wolpe says, they *reciprocally inhibit* each other: the arousal of one motivational system inhibits the arousal of the other (see *Reciprocal Inhibition* in Volume 1, Chapter 6). Although food is an extremely useful counterconditioning stimulus for moderating strong fears, it is of utmost importance that the dog's appetitive response be strong enough to overshadow its fear. If food is presented to an already fearful dog, the treat may become counterconditioned in an opposite direction; that is, food may become associated with fear—a highly undesirable and common outcome. The danger of inadvertent aversive counterconditioning is minimized by gradually exposing a hungry dog to minimally evocative samples of the fear-eliciting stimulus. It is also useful to vary the kind and amount of the food given to the dog at each step: surprise is a critical factor in using food as an effective counterconditioning stimulus.

Motor activity can also produce a mild counterconditioning effect by a process that Baum (1970) has referred to as *mechanical facilitation*. The critical issue is to maintain forward locomotion without evoking a freez-

Table 3.1. Stimulus dimensions affecting counterconditioning and desensitization efforts

Proximity: Most dogs tolerate the presence of a feared object, event, or person at a distance, but become progressively more fearful and reactive as fear-eliciting stimulus comes into close proximity (Figure 3.4). For instance, a distant roll of thunder may not have any discernible affect on thunder-phobic dogs until it reaches some critical proximity.

Context: Another important factor determining the fear-eliciting stimulus's relative strength is the influence of context. Exposure to a thunderstorm while the owner is nearby may be much less aversive for a dog than exposures occurring when it is alone. In addition to social variables, the environment itself may physiologically predispose a dog to fear (see Kallet et al., 1997).

Similarity: Besides proximity and context, dogs react differentially to the relative similarity between a presented stimulus and an actual feared object or event. Dogs unable to tolerate thunder may be able to accept other loud noises sharing some similar features with thunder (e.g., loudness and surprise). Such similar surrogate items may be selected in cases where the actual feared object or event is not readily available or easily tolerated.

Intensity: Fearful stimuli of low intensity are less provocative and more easily endured or habituated than more intense samples of the same stimulus. Recorded thunder effects played back at a very low volume are obviously much less frightening to a dog than when they are presented at full volume.

Duration: The duration of the fear-eliciting stimulus has a direct and significant bearing on the desensitization process. A dog is exposed to progressively realistic exposures as its tolerance will allow, but initially brief exposure to low-intensity stimuli helps to facilitate the process.

Frequency: Many fears are associated with extremely brief stimuli occurring within a fraction of second (e.g., gunfire), requiring that they be presented repeatedly. The frequency of presentation depends on a dog's response and recovery. Repeated exposure at low intensity appears to facilitate desensitization effects.

Predictability: Aversive stimulation occurring on a predictable basis is less fear arousing than when it occurs on an unpredictable basis. Anxiety can be interpreted as a state of vigilant arousal that occurs in response to a fear-eliciting stimulus that presents unexpectedly. Anxiety serves to lower fear thresholds, thereby competing with desensitization efforts. The infrequent, brief, and unpredictable occurrence of thunderstorms may significantly contribute to the development of storm fears via anxiety occurring during times of the year when storms are more common.

Controllability: Aversive stimuli and situations presenting with a high degree of controllability are far less provocative of fear and stress than are aversive stimuli that occur on a uncontrollable basis. Many fears reflect an underlying loss of confidence stemming from a lack of appropriate experience and skill or a history of failure with respect to the control of potentially dangerous situations.

Continuity: To be maximally effective, the desensitization hierarchy should have an even flow or continuity from lower items to higher ones. Sudden discontinuous jumps between items should be avoided.

ing or fleeing response. Making a dog move in a beeline toward a feared situation may rapidly overshadow the relaxing effects of motor activity with fear. It is often useful to approach the fear-eliciting situation on a slight curve, moving steadily away from the situation. Repeated passes may gradually result in closer and closer passes, evidencing fear reduction and decreased avoidance. While some benefit can be obtained by merely walking a dog near a fear-provoking situation, stronger effects are attained by periodic changes of pace (excited running), letting the dog find planted treats and engaging it in various play activities (e.g., tug games) while in the proximity of the feared situation. Mild fear can be modulated in some dogs by giving them a soft toy to carry. Toys stuffed with food can also be useful, especially if they are strategically hidden in a way that requires the dog to become progressively closer to the feared situation in order to find them. Prompting the dog to perform a series of well-conditioned obedience exercises and providing food and affection as rewards can be an extremely beneficial fear-

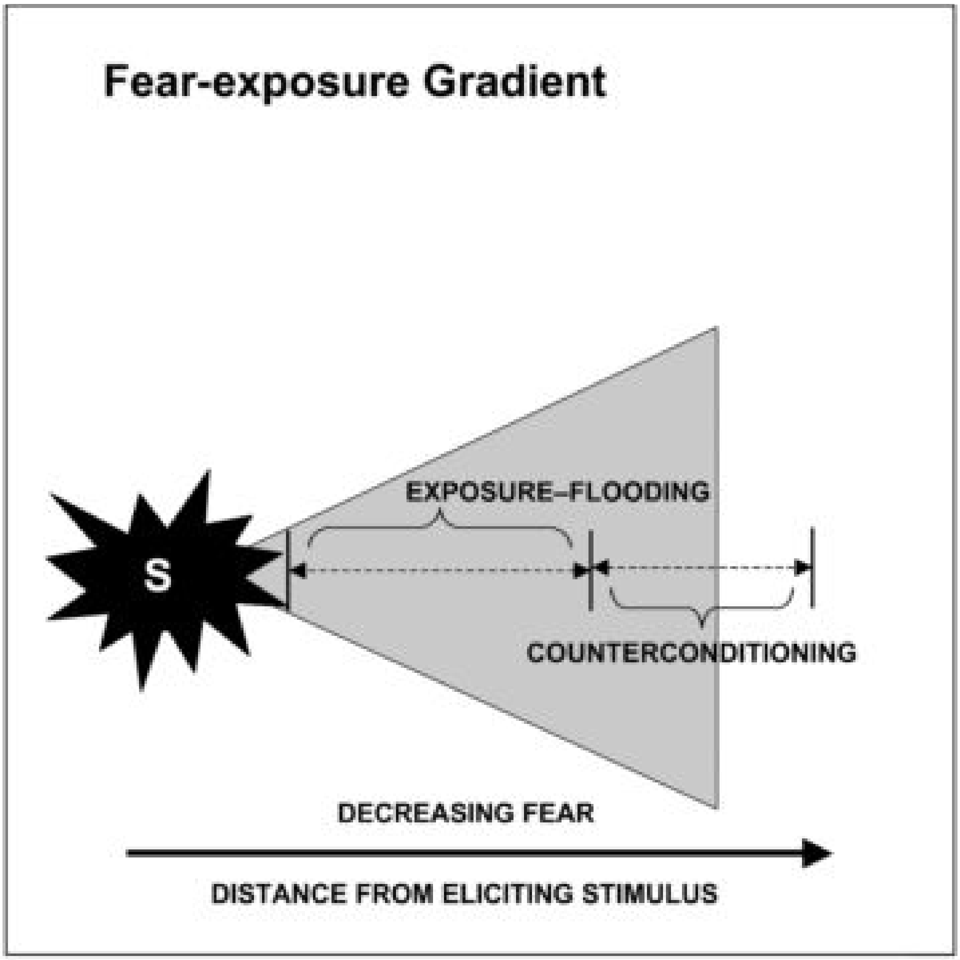

FIG. 3.4. Various stimulus dimensions, including distance, alter the capacity of a trigger stimulus to elicit fear. Effective counterconditioning is usually performed by evoking a state of arousal antagonistic to fear while exposing the dog to a minimally provocative fear-eliciting stimulus, whereas exposure with response prevention may be performed in the presence of more provocative trigger stimuli.

reducing technique, especially if a highly desirable reward is given for every correct response. Another powerful technique for modulating fear is structured postural manipulation together with relaxing massage and olfactory conditioning (see *Posture-facilitated Relaxation Training* in Appendix C), which appears to help restrain adverse emotional arousal and stress-related concomitants associated with fear. Finally, as previously noted, the presence of a confident canine cotherapist acting as a model for the desired behavior may facilitate the process through social facilitation and local enhancement (see *Social Learning* in Volume 1, Chapter 7). Model/rival play activity in which the dog is put on a tie-out and allowed to watch the trainer and owner tossing a ball back and forth and playfully interacting may inspire some dogs to lower their guard, especially in the case of highly sociable dogs showing a keen interest in the ball.

GRADED EXPOSURE AND RESPONSE PREVENTION

Although graduated counterconditioning may not be consistently effective in all cases and

may not be very efficacious as a stand-alone procedure for resolving conditioned fears, it does appear to provide benefit in many cases involving fear due to habituation deficits or adverse sensitization and remains a legitimate and useful tool for modulating fearful arousal in the context of behavior therapy, especially when used in combination with other behavioral procedures (e.g., graded interactive exposure, habituation, response prevention, attention therapy, and basic training). Perhaps the most important function of counterconditioning in the process of treating conditioned fears is to help modulate aversive arousal occurring in association with the graduated introduction of response prevention and to decrease anxiety associated with its fading and discontinuation.

Partial-extinction Effects, Response Prevention, and Behavioral Blocking

Conditioned fear is most effectively extinguished by disconfirming escape/avoidance expectancies (see *A Cognitive Theory of Avoidance Learning* in Volume 1, Chapter 8). In practice, fear is reduced under circumstances in which the escape/avoidance response is blocked, while the feared outcome is prevented and stimulation incompatible with fearful arousal is presented. Such treatment results in a condition of safety and fear reduction, but it may impede the full extinction of fear. Full extinction extends the partial-extinction effects obtained under the blocked condition to more natural unblocked conditions, thereby fully disconfirming the operative avoidance contingency. According to this interpretation, full extinction requires exposure to both blocked and unblocked conditions (see *Conditioned Fear and Extinction* in Volume 2, Chapter 3). As the result of response prevention, only the blocked condition is disconfirmed, leaving the unblocked condition untested; that is, the feared event might still occur when the blocking contingency is lifted. As such, the discontinuation of response prevention may generate significant apprehension and anxiety in response to the conditioned fear stimulus. Consequently, although response prevention may significantly reduce fear, apprehension and anxiety may occur when the safety of the blocking contingency is removed. By slowly fading the blocking contingency in association with counterconditioning, the risk of such anxiety can be significantly reduced; in turn, graded interactive exposure with response prevention can help to reduce the approach-avoidance conflict associated with stand-alone counterconditioning. The reciprocal benefits resulting from the combined use of response prevention and counterconditioning (RP-CC) strongly recommend that they be used together as complementary therapies in a comprehensive approach to the treatment of canine fears and phobias. In addition to disconfirming fearful expectancies, intensive basic training is seamlessly integrated into RP-CC procedures, with the goal of enhancing executive control functions (attention and impulse control) and improving the dog's ability to cope more competently with feared situations.

Response prevention is essentially a punitive contingency serving to disconfirm a dysfunctional control expectancy. In addition to physical restraint, avoidance control and safety training techniques might be considered in some cases to block escape/avoidance behavior and to reinforce incompatible behavior. A major potential advantage of such training is the internal relief/relaxation effects and safety associated with successful escape and avoidance (see *Safety Signal Hypothesis* in Volume 1, Chapter 8). Persistent and refractory fears stemming from sensitization or precognitive exposure to traumatic stressors may be responsive to an approach combining RP-CC and behavioral blocking. As the result of behavioral blocking via trained avoidance responses, fears operating independently of functional prediction-control expectancies might be brought under better functional executive control, thereby helping to mediate fear extinction via the formation of cortical inhibitory restraint over subcortical emotional fear memories. In addition to potential for restraining emotional fear, such training might help to reduce fearful behavior by consolidating fear-incompatible expectancies and emotional establishing operations in the presence of the fear-eliciting stimulus, thereby helping to modulate and normalize the dog's response to it. Behavioral blocking and avoidance training may produce significant

relief/relaxation, gradually causing the dog to feel safer in the presence of the previously feared stimulus or situation.

The current experimental literature indicates that graded interactive exposure and response prevention are the most efficacious means for reducing conditioned fear in animals (see *Interactive Exposure and Flooding* in Volume 1, Chapter 6). As the result of repeated safe exposures to the fear-provoking stimulus or situation (desensitization by habituation), the animal gradually learns that the feared situation is no longer predictive of aversive stimulation. Exposure works by extinguishing or habituating the fearful reaction, thereby disconfirming a dog's fearful expectancies and promoting a more adequately predictive and "reality tested" reaction to the evoking situation. When escape and avoidance efforts are blocked, many dogs eventually recognize that a threat no longer exists in the presence of the fear-evoking situation, a recognition that appears to produce relief and relaxation. Relief and relaxation following the cessation of aversive arousal provide a powerful counterconditioning influence (see *Response Prevention, Opponent Processing, and Relaxation* in Volume 2, Chapter 3). During graded interactive exposure, the dog is brought into closer and more varied contact and interaction with the evoking stimulus, thereby developing the confidence and skills needed to cope competently with the feared situation.

Graded Interactive Exposure

Graded interactive exposure is often combined with instrumental procedures in which trained behaviors incompatible with escape or avoidance are prompted and reinforced in the presence of a fear-provoking stimulus or situation. Preliminary attention and basic training consist of bridge conditioning, following and coming, orienting, sit- and down-stay, targeting, attending behavior, starting exercise, and controlled walking. The dog should be thoroughly desensitized to the fixed-action halter and kept on a hip-hitch and control lead or closed-loop system for added safety (see *Halter Collars* in Chapter 1), especially if manipulations tying up the hands are involved (e.g., using a squeaker, clicker, or food). In addition to prompting and reinforcing previously established control modules and routines in the presence of the feared situation, spontaneous approach behavior can be selectively reinforced via a DRO or shaping schedule of differential reinforcement while escape/avoidance behaviors are blocked. The idea is to encourage more competent behavior through successive approximations and spontaneous initiatives occurring in the absence of escape or avoidance efforts. In addition to overt dynamic and interactive behavior, shaping efforts can also be applied to static postural behaviors associated with increased confidence (e.g., tail relaxed or wagging, ears forward and alert, standing upright, leaning forward, not leaning on trainer or objects, and steady frontal orientation). Such training efforts exert both instrumental and classical conditioning effects incompatible with fearful behavior. Effective shaping depends on a well-conditioned bridging stimulus (see *Shaping Through Successive Approximations* in Volume 1, Chapter 7). The bridging stimulus is conditioned by repeatedly pairing a distinct auditory stimulus (e.g., "Good" or click) with the presentation of food and other rewards (e.g., affectionate petting and play). Both a vocal stimulus and a clicker-bridging stimulus should be conditioned to a high degree in the context of orienting training and controlled walking in advance of therapeutic applications. After several pairings, the bridging stimulus can be used to link or *bridge* desirable behavior with a spatially separated and delayed reward while at the same time evoking affects incompatible with fear. A squeaker bulb (without squeaker valve) scented with an odor (e.g., orange or lavender) is held in the right hand and squeezed just before the hand is opened to deliver treats. The conditioned odor can be subsequently used to augment appetitive counterconditioning efforts. Preliminary training should strongly focus on augmenting orienting and attending responses via the manipulation of positive prediction error and dissonance effects, using the dog's name or an orienting stimulus (e.g., a squeaker or smooching sound). Capturing the dog's attention in a decisive and timely way (i.e., at the earliest sign or link in the rapid

chain of events leading to the avalanche of emotional and behavioral events associated with fear) serves to interrupt and deflect fearful behavior, while enabling the trainer to redirect it toward activities incompatible with fear (see *Target-arc Training*). Many dogs trained in such a way adopt a coping pattern in which the feared stimulus prompts them to look toward the owner for support rather than balking, fleeing, or becoming reactive (e.g., compulsive barking).

The efficacy of graded-exposure training is influenced by a number of procedural constraints. Although exposure procedures can be extremely effective, they may make things worse when improperly performed. For example, repeated, *brief* exposures to intense fear-eliciting stimuli may increase fear and make subsequent exposure efforts more difficult. Exposure to the provoking situation should continue until fear subsides or is replaced by relief and relaxation. Also, unexpected and intense occurrences of the fear-eliciting stimulus may cause increased sensitization and dishabituation. This adverse influence is especially problematic when it is coupled with repeated, brief exposures to the intense sample. Many common fears appear to persist because the dog does not remain in the presence of the provoking situation long enough to benefit from slowly emergent opponent relief and relaxations effects. When startled, the animal simply hides or runs away. Interestingly, the brevity of intense loud noises (e.g., gunshots, fireworks, or thunder) may be a major factor in the development of phobias related to loud-noise stimulation. For example, thunderstorms are seasonal, they are brief, and they may involve intense acoustical stimulation capable of eliciting pronounced fear in predisposed dogs, independently of other sources of unconditioned aversive stimulation. Thunder-phobic dogs repeatedly exposed to these brief and traumatic experiences with thunder and lightning may become progressively sensitive to them as well as other phenomena related to storm activity. The periodic and intense nature of such stimulation precludes normal habituation and strongly recommends early preventive exposure in the case of dogs and puppies exhibiting a low startle threshold to noise (see *Habituation, Sensitization, and Preventive-exposure Training*).

Normally, following intense startle and fearful arousal, opponent relief and relaxation predictably follow the discontinuation of aversive stimulation (see *Safety, Relief, and Relaxation* in Volume 1, Chapter 3). Relief and relaxation appear to help restrain fearful arousal and to promote homeostatic adaptation following the aversive event. Relief occurs immediately after the aversive stimulus is discontinued and continues for 15 to 20 seconds. Relaxation is a more sluggish opponent process and begins to appear only after approximately 2 1/2 minutes after the aversive stimulus is withdrawn. To take full advantage of these effects, techniques involving the discrete presentation of fear-provoking stimuli should be spaced to maximize relief and relaxation effects. In addition, safety signals should overlap both relief and relaxation phases of postaversive adaptation. By pairing vocal cues (e.g., "Relax"), acoustical stimuli (continuous tones or music), various scents, and tactile signals (petting) with relief and relaxation, these combined redundant stimuli may gradually become conditioned safety signals predicting the absence of aversive stimulation (see *Fear, Cognition, and Avoidance Learning* in Volume 1, Chapter 3). Conditioned safety signals may function as conditioned inhibitors of fearful arousal (Hawk and Riccio, 1977) as well as evoke therapeutically beneficial conditioned safety-relaxation effects (Denny, 1976). As a result, conditioned safety signals provide a convenient means for reducing fearful arousal and encouraging more secure behavior when a dog is faced with a fear-provoking situation.

Rehearsal

Fearful arousal resulting in frantic escape or panic behavior is detrimental to the exposure process. If such behavior succeeds, a dog's reactive escape behavior may be strongly reinforced, leading it to respond in a similar way when exposed to the fear-eliciting situation in the future. Avoidance and escape behavior is incompatible with maintaining a progressively closer proximity with the threatening situation—a requirement for successful fear reduction. However, observing the feared stimulus

or situation at a safe distance, though comfortable for the dog, may not alleviate its fearful avoidance or promote confident behavior when it is brought into closer contact with the feared situation. The fearful dog must be gradually and systematically exposed to fear-provoking situations to optimize the effects of graded interactive exposure. Since fearful arousal may be increased by repeated, brief, and uncontrolled exposures to threatening situation, it is advisable that casual exposure to the fear-eliciting stimulus or situation be minimized.

Before exposing the dog to the actual fear-provoking situation, each step in the process should be rehearsed under minimally provocative conditions. For example, if the dog is afraid of strangers when they first visit the home, the various events and activities associated with such visits can be practiced in advance. Behavioral rehearsals include such activities as ringing the doorbell, leashing the dog, calling the dog to heel, training the dog to hold a sit-stay, opening the door, and finally appropriately reinforcing the dog's behavior. Most dogs enjoy going for walks, and the opportunity for such activity is associated with keen interest and anticipatory activity. Ringing the doorbell or knocking on the door before getting the dog's leash and going for a walk can help to countercondition aversive associations evoked by the sound of the bell. Whenever possible, taking the fearful dog for a walk with unfamiliar visitors is an effective interactive exposure technique. Not only are walks enjoyable, they can last long enough to moderate fearful arousal and facilitate relatively close and sustained interactive contact between a socially avoidant dog and people. Moreover, taking the dog outdoors and away from the home to interact with the visitor obviates confounding territorial issues that may complicate the situation.

To perform these various activities, it is imperative that fearful dogs learn to walk on a controlled leash, to perform the quick-sit without hesitation, and to hold a reliable sit-stay and down-stay. Such preliminary training should be practiced in every situation where the dog might potentially encounter the fear-eliciting stimulus. Food is a convenient reward, as it can be readily used as a counterconditioning stimulus, as well. Once all the elements have been trained and rehearsed, the next step is to stage the actual event by using a situation that is minimally provocative. Besides representing a positive in vivo exposure to a minimally evocative situation, such staging is a useful way to iron out any unforeseen difficulties that might emerge during more natural exposures later.

Staging and Response Prevention

Response prevention brings a dog into close proximity with the fear-provoking situation, thereby evoking low to moderate levels of fear that slowly undergo habituation. An important function of response prevention is to block undesirable escape and avoidance behaviors. Uncontrolled avoidance and reactive escape efforts hinder a dog's ability to unlearn the toxic emotional expectancy, thus forestalling the development of a more moderate and adjusted response to such stimulation. As the result of repeated uneventful exposures, the dog may gradually discover that its fear is unfounded and begin to experiment with more prosocial or exploratory behavior. Significant evidence suggests that the motor components of fear are localized in the basal ganglia (species-typical routines) and the cerebellum (skilled motor coordination), whereas the emotional aspects of fear are elaborated in the amygdala (Mintz and Wang-Ninio, 2001). This research suggests that fearful emotions and fear-related behavior are acquired and maintained in different parts of the brain. As the motor skills needed for successful avoidance are acquired, a significant reduction in fear arousal occurs. Motor competency appears to have a pronounced modulatory effect on emotional fear localized in the amygdala; however, reactive escape/avoidance behavior that does not provide enhanced control over the fear-eliciting stimulus may actually intensify fear. Fear-related motor output may have pronounced secondary effects on fearful arousal, especially if the animal's escape/avoidance efforts are frantic and disorganized. Consequently, such reactive responses to fear should be prevented or blocked and replaced with more competent and adaptive alternatives.

During the staging of in vivo graded exposures, a dog is presented with progressively more aversive situations, provoking arousal in amounts that won't overwhelm it with fear or panic. The reactive dog is forced to give up its escape efforts as useless by systematically blocking movement away from the feared situation. These blocking efforts are continued until the dog's escape efforts subside. Initially, keeping the dog in motion is generally superior to having it sit or lie down and stay in the presence of a feared situation; as its fear is reduced, sit-stay and down-stay exposures can be added gradually. In addition to outward curving or angling approaches from the feared situation (e.g., crossing the street), a circular or spiraling pattern can be used. As the pattern is walked off, various types of food reward are covertly dropped at varied distances from one another. As the circle is completed, the same pattern is walked off a second time and the dog is encouraged to find the planted treats. Another technique involves having a stranger walk away from the dog while dropping treats every so often, including an occasional big surprise, as the dog follows at a safe distance from behind picking them up. After repeated graded exposures with response prevention, the dog gradually discovers that there is nothing to fear, thereby becoming more receptive and responsive to counterconditioning and safety training efforts (see *Response Prevention, Opponent Processing, and Relaxation* in Volume 2, Chapter 3). Interactive exposure involves physically directing the dog to engage in behavior that it would probably not choose on its own. Restraining a fearful dog in the presence of a fear-provoking object or person is potentially risky, so appropriate precautions should be taken. Consequently, when performing response-prevention procedures, appropriate restraint and equipment should be used (leash attached to a fixed-action halter or limited-slip/halter combination). Under some circumstances involving potentially aggressive dogs, a muzzle-clamping halter or muzzle may be a necessary precaution. When highly aroused with fear or rage, dogs should not be coddled with reassurance and protective petting. Such handling is not usually productive under such circumstances, and it may inadvertently make things worse or result in a redirected attack.

Counterconditioning and Interactive Exposure: Final Steps

Response prevention is particularly important when bringing the dog into close contact with the feared object or persons. Getting through this final barrier often requires a combination of response prevention, attention training, counterconditioning, and behavioral blocking techniques. In addition to inducing postarousal relief and relaxation effects, response-prevention procedures serve to block and extinguish instrumental escape and avoidance behavior via the disconfirmation of dysfunctional prediction-control expectancies, thereby preparing the way for additional cynopraxic behavior therapy and training efforts. Although graded exposure with response prevention may rapidly reduce overt fearful behavior, additional appetitive and emotional counterconditioning and play therapy may be needed to antagonize lingering emotional fear and prevent excessive anxiety as the blocking contingency is removed. Finally, by incorporating and reinforcing trained behavior with a composite of social, appetitive, and ludic rewards, an augmented safety bias can be developed to help generalize more confident behavior over varied situations previously eliciting fearful reactions.

Approach behavior is supported by bridging (DRO and shaping), petting, massage, food, conditioned odors, and play in order to produce new, attractive, and complex associations with the situation, to enhance attention and impulse control, to strengthen more appropriate and diversified patterns of behavior, and to establish active modal activity (exploring, investigating, experimenting, and so forth) conducive to interactive competence. Again, planting the situation with highly palatable food rewards that the dog can easily find on its own or with the aid of the trainer pointing them out can be very useful for motivating seeking and exploratory activity. A conditioned odor can be introduced to further facilitate the transitional process. For example, an odor that has been repeatedly paired with food via a scented squeaker bulb

(squeaker valve removed) can be delivered quietly with a modified carbon dioxide (CO_2) pump or a scented squeaker bulb, thereby modulating aversive arousal and enhancing food-related counterconditioning efforts. The olfactory signature used to facilitate and conclude posture-facilitated relaxation (PFR) training may be incorporated to produce associations and arousal incompatible with fear and enhance counterconditioning efforts associated with tactile stimulation (e.g., long and firm strokes of petting and massage), perhaps hastening the recruitment of a relaxation response (see *Olfaction and Emotional Arousal* in Chapter 6).

Interestingly, many (but certainly not all) fearful dogs, once within close contact with the feared situation, rapidly begin to relax under the influence of response prevention and the presentation of conditioned odors. During such exposure, the dog is vocally encouraged, petted and massaged, and rewarded with different types of food presented in varied amounts and frequencies. Rewards are presented in association with a highly conditioned bridging stimulus in accord with a DRO or shaping contingency or in the context of attention training. A dog's willingness to accept food at such times is a propitious sign, because it indicates that fear is either attenuating or at least not increasing. In general, the dog's willingness to accept food is a fairly reliable, but not foolproof, way to monitor nascent emotional changes incompatible with fear, whereas the loss of appetite is a useful barometer for gauging fearful interference. Evidence of progressive relaxation in response to massage is also a promising indicator, since a dog cannot be tense and reactive while at the same time remaining relaxed and calm.

Targeting-arc Training

As the result of socialization deficits, abusive or traumatic handling, or behavioral stress (anxiety and frustration associated with disorderly social interaction), dogs may become progressively reactive, showing signs of hypervigilance, anxiousness or irritability, and an acquired inability to respond adaptively to signals of threat or loss (see *Inclusion Criteria* in Chapter 5). A chronic exposure to attractive and aversive stimulation lacking order and consistency may exhaust or degrade attentional and comparator functions, giving rise to persistent frustration, anxiety, or both (helpless-panic spectrum), and an inability to produce reward via executive mediated comparator networks and positive prediction error. As a result, such dogs may become progressively reactive to environmental stimuli, showing a preferential sensitivity toward signals of punishment (loss and threat) and an affinity for fight/flight reactivity. Such reactive-type dogs appear to be prone to develop fears as the result of aversive sensitization. Paradoxically, though, despite their enhanced sensitivity to signals of punishment, such dogs often show striking deficits with respect to avoidance learning and nociception, apparently obtaining little reward as the result of successful avoidance (see *Post-traumatic Stress Disorder* in Volume 1, Chapter 9).

Training the orienting response to a high degree of reliability is of critical importance and value in preparation for both graded interactive exposure and counterconditioning efforts (see *Attention and Autonomic Regulation* in Chapter 8). In the case of highly reactive dogs, however, a variation of attention training focusing on the targeting arc of several sensory-analyzer systems (i.e., auditory, visual, olfactory, tactile, and kinesthetic) may yield additional benefit as a starting point. Targeting-arc training (TAT) is based in part on distinctions drawn by Konorski (1967) between targeting and orientation reflexes (see *Targeting Reflex* in Volume 1, Chapter 6). The targeting arc is a rapid adjustment of a sensory analyzer to an environmental event, captured or sandwiched between an orienting stimulus (e.g., squeaker, hand movement, odor, touch, or prompt by leash) and bridge stimulus (clicker). The targeting arc is akin to a behavioral snapshot delineated by a stimulus response and a reward signal. For example, the auditory targeting arc consists of a slight sideways head movement or ocular orientation toward the source of stimulation. TAT is introduced in a relatively distraction-free environment with an ambient odor (e.g., orange

or orange-lemon mix) delivered by an aquarium pump and diffuser. During TAT, the dog is first trained to take food from a closed hand flicked to the side (see *Introductory Lessons* in Chapter 1). TAT is focused on the split-second adjustment when the dog alerts to the orienting stimulus, whereupon the trainer clicks and flicks the closed right hand to the side, causing the dog to approach and take the food reward. A squeaker scented with the ambient odor is gently squeezed just before the hand is opened to deliver the reward. The targeting arc is a micro-control module consisting of reflexive and instrumental elements and organized in accordance with an appetitive control incentive. Initially, TAT is performed in the context of a varied DRO schedule, but is gradually superseded by a shaping contingency (e.g., following the trainer's body or tracking the movements of the right hand) and training the dog to come, sit, stay, and attend (i.e., make and hold eye contact in response to its name).

As a gate between the environment and executive analyzing and organizing functions, the targeting arc mediates selective attention and impulse control, providing an anchor for subsequent training and a conduit for manipulating appetitive and emotional establishing operations. If trained by ordinary means, using a repetitive orienting stimulus and a highly predicted reward, the orienting response rapidly habituates and plateaus. However, by varying the sound of the squeaker and presenting variable rewards on a DRO schedule conducive to positive prediction error and dissonance effects, a highly potentiated orienting response is produced, perhaps helping to refresh and restore attention functions and renewing the dog's interest in reward, as well. In addition, since positive prediction error is conducive to adaptive modal activity, TAT provides a viable organizing platform for reward-based training and therapy efforts (see *Instrumental Control Modules and Modal Strategies* in Chapter 1). Attention therapy with TAT may help disorganized dogs to transition gradually from a reactive cognitive and emotional orientation to a more adaptive one that shows an increasing sensitivity and responsiveness to signals of reward and punishment.

PART 2: FEARS AND PHOBIAS: TREATMENT PROCEDURES AND PROTOCOLS

Dogs are prone to develop fears and phobias toward a wide variety of eliciting stimuli and situations (see *Phobia* in Volume 2, Chapter 3). Many of these problems are discussed in Volume 2. The purpose of the following is to examine common phobias and to explore various methods for reducing them (see *Classical Conditioning and Fear* in Volume 1, Chapter 2). Remedial training for phobic dogs follows a regular course of events regardless of the specific fear involved. The first step is to define the functional and structural limits of the problem accurately, that is, the what, when, where, and how of its occurrence (see *Assessment and Evaluation of Fear-related Problems* in Volume 1, Chapter 3). This information can then be used to select an appropriate training program. Most of the fear-reducing techniques described are based on experimental studies involving fears produced by aversive conditioning, typically involving electrical shock; that is, the studies are largely limited to understanding the acquisition and extinction of the fear of pain. Fearful behavior presented by companion dogs is typically far more complicated, and the originating causes are often unknown and may emerge quite independently of any identifiable experience of pain. Further, it is virtually impossible to duplicate the highly controlled conditions of a laboratory in a home or clinical setting (Baum, 1989). Consequently, in addition to scientific knowledge, a significant amount of common dog sense and creative problem solving is needed to treat canine fears and phobias successfully, making cookbook protocols quite beside the point.

FEAR OF PAIN AND DISCOMFORT

Common fears associated with pain include grooming, handling, nail clipping, various veterinary procedures, and improper training procedures. Many conditioned fears associated

with pain can be prevented by means of latent inhibition and other habituation procedures performed early in the dog's development (see *Habituation, Sensitization, and Preventive-exposure Training*). Some dogs appear to be more sensitive to touch and prone to develop persistent fears associated with discomfort and painful handling. The usual procedures used for resolving such problems employ some combination of graded interactive exposure with RP-CC. Although conscientious efforts should be made to countercondition a fearful dog with treats and relaxing massage while it undergoes progressive exposure to the feared activity, it is imperative that avoidance and escape be blocked. Very often in such cases counterconditioning efforts will achieve only a small portion of the desired effect. Response prevention using physical restraint followed by massage as the animal begins to relax can be very useful. It is important for the dog to become relaxed before it is released from restraint. In the case of dogs that become highly reactive, they should be held in restraint (with massage) for 3 additional minutes after the last strong effort to break free. Excessive sensitivity to touch and contact aversion appear to play significant roles in the development of some aggression problems. Dogs exhibiting pain-based fears may resort to aggressive efforts to escape restraint during response-prevention procedures. Consequently, a muzzle or other adequate restraint may be necessary, at least until the dog learns to recognize that it is safe and will not be hurt during the training procedure. Persistent fears based on past painful experiences are usually responsive to graduated exposure with response prevention and counterconditioning.

STORM AND THUNDER PHOBIAS

The vast majority of noise phobias involve thunder or loud percussive sounds such gunshots or firecrackers. Shull-Selcer and Stagg (1991) reported that 93% of cases (N = 30) of dogs with noise phobias involved fear of thunder and other loud noises (e.g., gunshots, fireworks, backfiring, or cap guns). Occasionally, a critical precipitating event can be traced in a dog's history that helps to explain its fear of loud noises, such as a particularly strong aversive event that has occurred in close association with the eliciting noise. Perhaps the most common cause is sensitization resulting from intense exposure to a loud noise (thunder, fireworks, gunfire, and so forth). Such highly aversive events may permanently alter a dog's fear and escape thresholds by sensitizing alarm-threat pathways mediating fear and startle (Koch, 1999), making it excessively reactive to noises and prone to exhibit persistent fear in response to minimal provocation. Finally, some dogs may simply exhibit a strong genetic predisposition leading to increased sensitivity to loud noises and a low-threshold acoustic startle response (Royce, 1955).

Prognostic Considerations

Unlike conditioned stimuli that acquire their fear-eliciting properties by way of startling or traumatic events, thunder phobias may develop with little or no evidence of extraordinary associative conditioning; that is, they are biologically prepared (see *Biological Predisposition and Preparedness* in Volume 2, Chapter 3). Further, in the case of noise-sensitive dogs, thunder and other loud percussive noises represent an unconditioned source of startle and fear. Stimuli that evoke fearful reactions without conditioning may do so through reflexive and hardwired neural pathways that may be shielded from the effects of graduated exposure, habituation, and counterconditioning—procedures that are notoriously prone to rebound effects, spontaneous recovery, and other savings (Kehoe and Macrae, 1997; see *Spontaneous Recovery and Other Sources of Relapse* in Volume 1, Chapter 6). Several other factors mitigate the effectiveness and efficacy provided by these procedures in the case of storm and thunder phobias. Most dogs that are afraid of thunder can learn to tolerate recordings of thunder if the sound effects are presented at sufficiently low levels while they are being massaged or eating food; they may even gradually accept more realistic recordings and loud playback of thunder sounds, but the conditioning may not transfer to other situations involving the actual sounds and ambient stimuli associated with real storms. Further, the benefits of countercondi-

tioning are largely dependent on the presence of the owner together with unconditioned stimuli (e.g., food and massage) evoking arousal incompatible with fear.

Unlike many common fear-eliciting situations, avoidance and safe escape from storm activity are not possible, although a dog may find some degree of momentary relief by hiding or clinging to the owner. Since avoidance and escape are not practical coping strategies, it is imperative that emotional fear be modulated through a variety of means. With help, highly fearful dogs can learn to cope passively with their fear of thunder (ultimately this may be the best that one can expect), but such efforts may not result in permanent change. Controlling fear associated with thunderstorms can be extremely frustrating and subject to recovery and relapse effects. Excessive fear represents a significant welfare concern and, in cases involving extremely fearful dogs that show a refractory response to behavior therapy, veterinary medical intervention should be considered. Behavior therapy combined with appropriate anxiolytic medication can make the process less stressful for both owners and dogs. Providing thunder-phobic dogs with prophylactic desensitization and medication during times of the year when storm activity is most likely to occur may help to modulate or manage symptoms, perhaps the best that one can expect in severe cases.

The prognostic picture for moderately fearful dogs is much better. Even in the case of moderate storm phobias, though, controlling fear of thunder is complicated by a variety of difficulties. The foremost difficulty in this regard is that thunder is not easily predicted and controlled. For example, a dog may be at home alone while the owner is at work when the storm occurs, making it impossible to organize appropriate fear-reducing efforts to head off excessive fear. This consideration is particularly relevant to separation-anxious dogs, whose distress at being left alone may add to their susceptibility to thunder-elicited fear. Even under ideal conditions, with the owner present, control over the frightening event is compromised to the extent that its intensity varies widely according to the strength of the storm and where lightning happens to strike. This lack of control also extends to various antecedent and extraneous stimuli (contextual influences) associated with the thunder itself. Ultimately, the best approach to managing thunder phobias is by means of preventive-exposure training (latent inhibition) starting at an early age (see *Habituation, Sensitization, and Preventive-exposure Training*). Since the exact causes underlying the development of storm and thunder phobias are unknown, methods for preventing them are based on reasonable speculation and training lore. Many young dogs show some degree of apprehension with the approach of a storm and may exhibit signs of growing fearful arousal during thunder and lightning. Encouraging confidence at such times by engaging them in tug games or ball play may be very useful. Going for walks in the rain, playing fetch, or having the dog perform a set of basic training exercises as the storm approaches may also help it to cope better with storms.

Behavioral Signs and Indicators

As a storm approaches, dogs may become progressively nervous and apprehensive, often seeking close contact with the owner or anxiously searching about the house. Fearful arousal intensifies as the storm nears, causing dogs to increase fearful activities and present increasing signs of restlessness and sympathetic arousal (e.g., panting and trembling). Some dogs may seek close comfort contact, leap on the owner's lap, or search frantically for a place to hide. Upon hearing a lightning strike nearby, fearful arousal may become even more pronounced and panicked. If outdoors, dogs may attempt to run off or dig back into the house (Voith and Borchelt, 1996). Other dogs kept inside the house may search for a way outside, often resulting in significant damage to window casings and door frames; some highly aroused dogs have jumped through glass windows and screens. Finding that escape is not possible, they may run to a bedroom or other areas of the house in search of safety. Many thunder-phobic dogs hide in closets, where they may cause significant damage to flooring and drywall by scratching and digging.

In an internet survey, McCobb and colleagues (2001) found that nearly 50% of those dogs that hide do so in bathrooms. Some of these dogs appear to be particularly attracted to tubs and showers as places of retreat. Theorizing about the motives compelling dogs to seek out tubs and other bathroom fixtures, Dodman (1996) has fashioned a dubious hypothesis to explain this predilection of canine thunder phobics. Based largely on reasoning from anecdotal evidence and hearsay, he speculates that static electricity may play a powerful role in the etiology of storm phobias. The theory purports that dogs may receive static electrical shocks during storms, causing them significant fear and distress. According to Dodman's hypothesis, fearful dogs may be seeking metal pipes and other grounds (water) to discharge static electricity safely from their bodies, which he believes builds up in their coats during storms. Years ago, Whitney (1964) proposed a similar theory, suggesting that some thunder phobias may be related to storm-related electrical stimulation. Whitney argued that dogs may be more sensitive to small electrical shocks than are people because dogs have greater amounts of salt in their blood. To reduce the risk of static shock, Dodman recommends various measures to prevent and reduce static buildup (Dodman, 1999), such as misting the dog with water, rubbing it down with a used sheet of fabric softener, or treating its feet with an antistatic spray. Unfortunately, very little in the way of compelling data or empirical evidence is provided to support the static electricity theory.

Social Contagion and the Fear of Thunder

Some authorities, most notably Beaver (1982, 1983), have suggested that storm and thunder phobias may be facilitated by a social contagion and reward. According to this theory, storm phobias are learned or worsened as the result of social attention given to dogs by owners during storms:

> Lightning striking nearby is a neutral stimulus and a dog continues sleeping. The frightened owner pats the dog (an unconditioned stimulus) mostly for self-assurance. The dog quickly learns that it will receive social attention during thunderstorms and that trembling will increase the amount of attention. (1982:1348)

There are a number of problems with Beaver's notion of contagion-mediated fear. First, lightning and thunder are far from neutral; actually, thunder is a potent unconditioned stimulus capable of eliciting intense fear in a sensitive dog. A fear of lightning and thunder does not need the owner's help to be learned. In fact, loud noises can be used to support fear conditioning or to rapidly suppress behavior. If anything, lightning in the aforementioned scenario is a neutral stimulus related to thunder as an unconditioned stimulus eliciting fear. The function of the owner's pat might serve as an unconditioned stimulus in so far as it evokes an antistress response (see *Origin of Reactive versus Adaptive Coping Styles* in Chapter 4), but it is extremely doubtful that such contact comfort would evoke or mediate fear. As a result of the close forward association between lightning and thunder, distant flashes of lightning in the future may evoke in the dog an anticipatory apprehension of an impending thunder event, causing it to become uneasy with conditioned fear. Second, far from evoking fear-related behavior, social attention and petting under such conditions might actually help to attenuate a dog's fear, perhaps helping to avert excessive arousal and sensitization to the sound of thunder. Third, and importantly, many signs of fear, such as trembling and panting, are bodily expressions of involuntary sympathetic arousal that are not under the control of instrumental contingencies of reward and punishment. A dog may be able to control certain aspects of its behavior when under the influence of fear, but activities such as trembling are not among them.

To the best of my knowledge, no significant evidence exists to support the belief that phobias are acquired or worsened through social rewards. Strong contrary evidence does exist, however, supporting the view that contact comfort may provide a significant source of anxiety and fear reduction for dogs and

may be useful for reducing fearful arousal in the context of behavior modification (see *Effect of Person* in Volume 1, Chapter 9). The key is to provide such contact and reassurance in a constructive way that helps to modulate fearful arousal and guides the dog into more appropriate coping behavior. In some cases, it may be essential that the dog learn to seek refuge with the owner rather than pacing about aimlessly or running away to hide. The big problem with providing affectionate reassurance and petting for fearful dogs is that they may come to rely on the owner's emotional support rather than learning to cope with fear on their own. Unfortunately, this is an inherent problem with most counterconditioning efforts. While petting and vocal reassurance may inadvertently support active avoidance, the effect of social attention and contact is probably minor in comparison to the reward produced by the act of successfully moving away from or avoiding contact with the provoking stimulus or situation. For the majority of dogs, the reward maintaining avoidance behavior is the avoidance of the feared situation or stimulus. Owner-mediated reinforcement of avoidance behavior is primarily the result of allowing the avoidance response to succeed, with subsequent affection and reassurance provided by the owner paling in significance to the intrinsic relief and relaxation associated with successful avoidance (see *Fear and Instrumental Reinforcement* in Volume 2, Chapter 3).

Finally, the belief that thunder fears may be transmitted as a contagion that is transmitted from the owner to the dog is not supported by research designed to evaluate the effect of human anxiety on dog behavior problems (O'Farrell, 1997). Although anxious individuals appear to be more disturbed by their dog's phobic tendencies, O'Farrell was unable to find a significant correlation between the anxiety levels of anxious owners and the development of phobic behavior in their dogs. Social contagion may play a role in the etiology of some common behavior problems (see Speck, 1964), including some fear-related problems (Howard, 1992), but it does not appear to play a prominent role in the development of thunder or loud-noise phobias.

Evolutionary Significance of Escape Patterns

Dogs show a fairly typical profile of fear and panic behaviors associated with storm phobias, suggesting that their reactions may belong to a common phylogenetic origin. This general hypothesis suggests that phobias are not dependent on learning for acquisition (Menzies and Clarke, 1995), although learning may play a significant role in the maintenance and generalization of fear to incidental neutral stimuli present during the fear-eliciting event. The primary instinct evoked under such circumstances is self-preservation, as evidenced by the dog's extreme arousal and efforts to escape the stimulation. Perhaps, at least in some dogs, storm activity involving lightning and thunder may directly activate primitive species-typical subroutines dedicated to maximizing survival when faced with natural catastrophes associated with lightning and thunder. Trapped within a house, dogs may feel threatened and vulnerable, causing them to run about in search of cover. As their fear and vulnerability increase, they may resort to other species-typical escape activities, such as biting, digging, and scratching. The failure of these various coping and escape efforts to obtain relief may stimulate a spiraling escalation of fearful arousal. Under future circumstances, frustrated escape efforts, now conditioned predictors of failure, may become potent elicitors of escalating fear. These observations underscore the importance of response prevention in the control of fear-related behavior.

Systematic Desensitization

Playing recordings of storms and thunder at progressively louder levels while dogs are maintained under the influence of incompatible arousal of sufficient strength to antagonize fear is the most frequently recommended method for reducing thunder phobias. While thunder sounds can be recorded and played back at varying volumes and degrees of realism, many aspects of the storm situation and ambience cannot be reliably replicated: illusion of sound coming

from a distance, window and wall vibrations resulting from thunder, changes in barometric pressure, dark and overcast skies, increased humidity and rain, realistic lightning flashes, sounds of wind and rain on windows, ozone level changes, and many other subtle nuances remain outside of direct manipulation or duplication. Also, given a dog's sensitive sense of smell, ambient odor changes associated with impending storm activity may play a significant role as a conditioned stimulus or contextual cue (Otto and Giardino, 2001). Furthermore, no recording can faithfully capture and duplicate the temper and violence of an actual thunderstorm. Consequently, many dogs that appear to respond positively to an artificial arrangement may do so knowing that the stimulation is not real. Most dogs rapidly learn to ignore recorded storm sounds, strobe flashes, subdued lighting, and so on, but probably do so knowing that the recorded sound and other effects originate safely within the house and while the owner is nearby. When left alone or when exposed to a real storm, previous desensitization efforts may not do much good. Since the beneficial effects of counterconditioning depend on the presence of emotional arousal that is incompatible with fear, any benefits acquired as the result of desensitization may be lost when an actual storm strikes, simply because the owner is not present to provide the accustomed appetitive stimulation, massage, and contact comfort.

The first step in the desensitization by counterconditioning is to determine whether the audio storm recording elicits a fearful response. If the recording proves effective, the next step is to find an audio level that is sufficient to evoke orientation but without eliciting fear. The thunder-phobic dog is initially exposed to the least evocative item on the list and then progressively challenged with more intense audio samples until the entire stimulus-gradient hierarchy is covered. Many variations are possible depending on a dog's temperament and the severity of its phobia. The desensitization hierarchy is treated as a guideline open to adjustment and modifications as they may prove necessary during training. The hierarchy should be as simple and short as possible, with additional items added as training progresses and such alterations prove necessary. Each step of the hierarchy should be worked on until both visible and inferred (anorexia) signs of fear are extinguished.

The key to successful desensitization is gradual exposure to as many features of the evoking stimulus and situation as possible, while at the same time maintaining the dog in a motivational state that is incompatible with fearful arousal. Several stimulus and situational dimensions should be considered when constructing an artificial desensitization hierarchy: similarity to the evoking stimulus; proximity (distance from the evoking stimulus has a significant bearing on the magnitude of the response); context (the presence of the owner, for example, during desensitization has a significant effect on fear levels; this the effect of person must be faded out gradually); intensity of stimulation (a loud sound typical elicits more arousal than a soft one); contrast (relative to surrounding ambience and competing stimulation); and stimulus continuity (whenever possible, evoking samples should be presented in a smooth progression of fear-eliciting increments).

The key to effective desensitization by counterconditioning is careful progression and patience. Between regular training sessions, a previously desensitized level of recorded thunder may played for extended periods for added benefit, especially at times associated with play activities and eating. By using an electronic timer, such samples can also be presented at low and progressively louder and more natural levels while the owner is out of the house.

The controlled circumstances of crate confinement are conducive to desensitization, but the crate must be introduced gradually and patiently with counterconditioning in order to avoid negative associations (see *Guidelines for Successful Crate Training* in Chapter 2). An air-pump odor dispenser and feeder is an easy way to deliver food rewards and olfactory stimuli while a dog is in a crate (Figure 3.5). The device is constructed from an aquarium air pump and a modified water dispenser. Air pressure is directed through pliable tubing and controlled by a touch valve and a three-way valve that diverts a

small amount of air pressure to a glass diffuser that is used to deliver a dilute odor. The air pressure directed to the diffuser should be adjusted to produce a minimal airflow, ensuring that most of the air pressure remains available to dispense the food. The tubing is attached to the water bottle by a plastic connector inserted into a small hole drilled into the side of the bottle. Also, to allow food to pass through the stem of the water dispenser, the steel-ball valve must be removed. As air pressure builds up in the water bottle, the soft food is forced out through the stem of the water dispenser. Since the air in the diffuser moves more freely than the air going into the water bottle, the arrangement results in the odor reaching the dog a second or two before the food is delivered, thereby providing a viable classical condition arrangement.

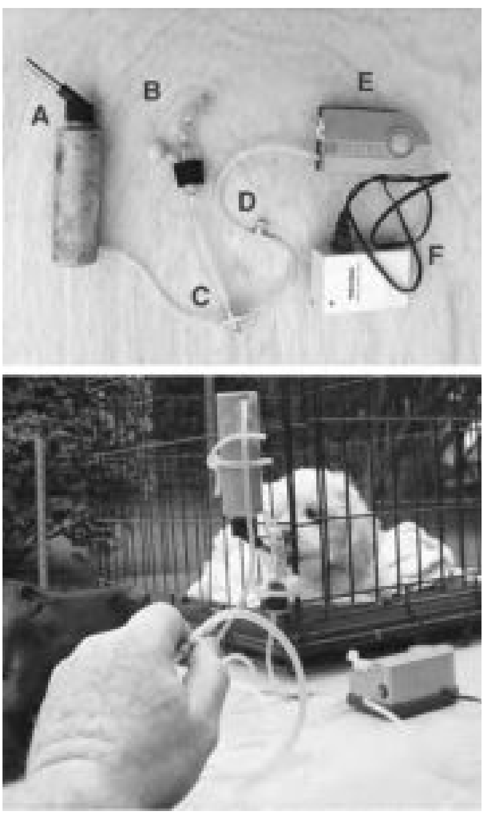

FIG. 3.5. Odor dispenser and feeder: (A) modified water dispenser, (B) glass diffuser, (C) three-way valve, (D) touch (screw) valve, (E) air pump, and (F) remote switch.

A touch valve situated in the main tubing regulates air pressure and allows the trainer to turn the odor and food presentation on or off. When the touch valve is covered with a finger, the air pressure rapidly builds and dispenses first the odor and shortly thereafter the soft food. When the finger is lifted from the touch valve, pressure is lost, and the odor and food stop dispensing. For remote operation, the touch valve can be sealed with a screw stopper, and a remote switch can be used to activate the air pump and control the delivery of food. This arrangement allows the trainer to stage desensitization conditions that more closely mimic situations when the owner is not at home—occasions when many phobic dogs are particularly vulnerable to thunder and other fears.

The persistence and resistance of storm phobias to extinction and desensitization efforts may, in part, be due to the brief duration of storm activity. Thunder storms typically roll in and roll out rapidly, perhaps not giving the dog sufficient exposure time to the stimulation to habituate naturally. As the storm subsides, the dog may experience significant emotional relief, negatively reinforcing preceding escape efforts, even though they had no effect on the storm's coming and going. Further, because the motivational arousal is extremely high, the potential effect of reinforcement at such times may be extremely strong and perhaps sufficient to establish persistent superstitious escape/avoidance behaviors. As a result, storm-associated cues may gradually become discriminative stimuli and establishing operations, setting the occasion for fear-related escape and avoidance behavior in the presence of stimuli associated with a storm. Consequently, during desensitization, dogs may be permitted to move around the room, but are not permitted to run off or hide. Efforts to hide or escape are prevented by keeping the dog on a leash or other restraint, as necessary. Some dogs may benefit from being restrained on a halter-type collar, an arrangement that enables the handler to control even very subtle escape/avoidance behaviors. Prior to performing desensitization procedures, the dog should receive intensive attention and basic training (see *Graded Interactive Exposure*).

Sample Hierarchy

Baseline information about a dog's reaction to thunder should be recorded, including various signs of fear. A chart and behavior journal should be kept to record procedures used and the dog's response to therapy. Heart rate is a sensitive measure of fear and should be measured and recorded at the beginning and end of each session. The outline of desensitization by counterconditioning described below is intended to provide a general picture; many variations and intermediate steps and subsets may be involved, depending on the specific requirements of a dog:

- The dog is exposed to low-level audio recordings of storm sounds (15 to 30 minutes or longer) while moving about, playing tug, chasing a ball, or receiving food and petting after coming when called. All efforts to leave the situation are prevented by keeping the dog on leash. Food rewards can be delivered from a hand holding a scented squeaker bulb. The bulb is squeezed just before the hand is opened to deliver the reward. Presenting the conditioned odor during simulated and real storms may augment appetitive counterconditioning effects. The conditioned odor is presented via an aquarium pump and diffuser before turning on the recording and continued for 3 to 5 minutes afterward. An easy-to-construct diffuser can be made with some rubber tubing and a small bottle with a cap (see *Taction and Olfactory Conditioning* in Chapter 4).
- The dog is exposed to low-level audio recordings of storm sounds under subdued lighting, flashes of light (camera strobe), and a fan blowing curtains while the dog moves about, plays tug, chases a ball, or receives food and petting after coming when called.
- The dog is exposed to a progression of stronger audio sounds of thunder with subdued lighting, remote flashes of light, a fan blowing curtains, and a sprinkler casting water against a window while the dog moves about, plays tug, chases a ball, or receives food and petting after coming when called. Previously desensitized levels are presented randomly during the day while the dog is playing, eating, or sleeping.
- The dog is exposed to increasing intensities (starting at a low level) of audio-recorded sounds while receiving PFR training.
- The dog is exposed to a progression of stronger audio sounds of thunder under subdued lighting, remote flashes of light, and a fan blowing curtains while the dog is in a crate receiving treats.
- The dog is exposed to taped recordings of thunder at natural intensity along with other storm-related sounds and movements while in a crate, with the owner on the other side of the room.
- The dog is exposed to taped recordings of thunder at natural intensity along with other storm-related sounds and movements while in a crate, with the owner out of the room.
- The dog is taken outside in the presence of an advancing storm and walked and engaged in various training activities, tug games, and ball play. Attention control is maintained by calling the dog's name, squeaking or smooching, and reinforcing appropriate orienting behavior.

At the conclusion of each step, the audio storm should be gradually turned down, mimicking the retreat of an actual storm. Perhaps the most effective use of counterconditioned audio storm recordings is to present them during actual storm events, thereby providing means to continue stimulation for a sufficient time to promote habituation and extinction and to reinforce behavior incompatible with fear. Counterconditioned audio storm sounds may exert a significant restraining influence on fear occurring in the presence of actual storms. The conditioned odor is presented just before the storm appears, followed by the audio storm, and continued during the full duration of the storm. The audio storm should stay on even after the actual storm has subsided, and continue until the dog's fear attenuates. The olfactory stimulus should be continued for 3 to 5 minutes after the audio storm is gradually tapered off. The combined presentation of the counter-

conditioned audio storm and the conditioned odor may help to dampen fearful arousal elicited by an actual storm event (see *Safety Signal Hypothesis* in Volume 1, Chapter 8). In some cases, earplugs fashioned from pliable silicone may be helpful, at least temporarily. A short knotted string should be imbedded in the silicone wad to make its removal easier.

Fear of Loud Noises and Household Sounds

A dog's response to loud noises is mediated by a variety of physiological and behavioral systems. Startle to loud sounds is reflexive and depends on genetic predisposition (sensory and behavioral threshold variability) and experience. The evoked startle response triggers a cascade of biobehavioral events preparing dogs for defensive action. Dogs exhibiting a low acoustical threshold may exhibit a very pronounced startle response to loud percussive sounds (e.g., gunfire or fireworks), even when they occur at some distance away, whereas dogs with a high acoustical threshold may simply orient in the direction of stimulation or ignore it altogether unless it occurs nearby. A dog's response to startling stimulation appears to be strongly affected by genetics, but experience exerts a powerful modulatory influence over functional thresholds controlling the latency and magnitude of the canine acoustical startle response. An increased responsiveness to auditory stimulation can be produced by fear-potentiated startle and sensitization (Koch, 1999). In the presence of ambient stimuli previously paired with aversive stimulation, loud noises or unfamiliar sounds may produce a potentiated startle response even though those auditory stimuli had never been paired with aversive stimulation in the past. For example, excessive punishment may result in the owner becoming a conditioned aversive stimulus. In the presence of such an owner, a dog's response to auditory stimulation may be significantly potentiated as the result of fear. Similarly, a wide variety of aversive conditioning events can permanently alter startle thresholds to auditory stimulation. Such fear-potentiated startle can have both adverse and beneficial effects on a dog's training and adaptation.

Sensitization occurs when a dog is exposed to an intense and unexpected auditory event, which subsequently results in significantly lower acoustical thresholds in response to that sound and other loud noises, as well. Sensitization appears to have played a role in the following case described by Humphrey and Warner (1934):

> One day she stopped him for a curb at a street crossing and waited for a large truck, halted by the traffic lights, to move on. As the lights changed and the truck started it back-fired in the face of the dog. The master, who was shell shocked as well as blind, jumped backward, yanked, stepped on and fell over his dog. Thus, the ear-pain from the back-fire was followed immediately by the body-pain of the trampling. The animal was retired from blind-leading at once because it was found that she had become extremely oversensitive to sound. After a year's service as a companion in a private home she seems to have outgrown the effects of the shock and to have become again gun-sure. She has not been returned to blind guide work, however, for it is feared that in a difficult traffic situation the occurrence of another noise, even though not so loud this time, might cause her to act erratically and endanger her man. (151)

The authors attribute the dog's fear to a conditioned association between the sound of backfire and painful stimulation, but a more likely cause is sensitization and the ensuing chaos and loss of control and predictability associated with the event.

Dogs exhibit varying degrees of stress-related behavior and physiological changes in association with noisy environments. Although many dogs appear to be remarkably undisturbed by loud noises so long as they are presented in nonstartling increments, sudden and loud noises may produce a surge of adrenal hormone activity indicating HPA-axis activation (Stephens, 1980). Thalken (1971) found that laboratory beagles exposed to a total of 2 hours of loud noise (120 dB) in repeated 30-second to 5-minute doses over an 8-hour period did not exhibit a significant increase in glucocorticoid activity. Similarly, Beerda and colleagues (1997) found minimal heart-rate and cortisol changes in dogs exposed to moderate stimulation levels under 87 dB. However, one dog exposed to 95-dB auditory stimulation for several minutes

showed increased cortisol activity and other signs of behavioral stress: tongue exposed, nose licking, paw lifting, and shaking. In a subsequent study involving strong, momentary auditory stimulation, the authors reported that repeated exposure to a momentary blast (1 to 2 seconds) from a foghorn (110 to 120 dB) resulted in significant physiological and behavioral evidence of stress, including a pronounced cortisol surge that returned to baseline levels after 60 minutes (Beerda et al., 1998). The researchers also found that the blast of the foghorn produced more cortisol activity than produced by moderately strong levels of repeated brief electrical stimulation delivered by a remote electronic collar (Tri-tronics 100 A set at level 8). Loud barking and other sources of noise are common in situations where dogs are housed together, with noise levels frequently exceeding 120 dB in kennel situations (Sales et al., 1997). Thalken's findings do not necessarily suggest that exposure to loud noise is not stressful; instead, the apparent absence of stress may be the result of previous exposure and habituation to loud noises in the dogs studied. Also, Thalken's failure to find evidence of stress in response to loud auditory stimulation may be attributable to breed-specific peculiarities affecting auditory arousal in beagles. As hunting dogs, beagles may have been selected to exhibit an elevated acoustical threshold for loud noises, enabling them to work in close range to the blast of a shotgun. In fact, dogs of different breeds exhibit varying levels of emotional reactivity to startle-eliciting stimulation (Mahut, 1958), making generalizations concerning fear and stress in dogs based on the study of a select breed or small group of represented breeds highly questionable. Finally, there is significant individual variability in the way dogs respond to startle- and fear-eliciting stimulation, further militating against such generalizations.

Desensitization by counterconditioning or habituation follows the same basic procedures as already described. The fear-eliciting effects of loud noises can be attenuated either by presenting them at a distance or by various muffling techniques. Hart and Hart (1985) have described a method whereby a nest of six cardboard boxes is used to muffle the sound of a starting pistol. Removing one box at a time, progressively making the sound stronger, produces a graduated effect necessary for desensitization. A more convenient method, and one that allows dogs and handlers to move about freely indoors and outdoors, is to wrap the starting pistol in a towel. Unwrapping the pistol one layer at a time gradually increases the intensity of the sound produced, thereby providing a means to present progressively louder samples of gunfire. Another way to present fear-eliciting noises on a gradient of intensity is to have a helper approach at various angles or orientations relative to the dog while periodically firing the pistol. Graded exposure can also be carried out with the dog on a 50-foot long line, allowing it to move to a safe distance before discharging the pistol or cap gun. As the dog starts in response to the stimulus, it can be called back, rewarded, and released again. In cases, where more precise control over the dog's distance is required, an active-control line can be used instead.

In addition to presenting the fear-eliciting stimuli on a gradient of increasing intensity, various conditioned and unconditioned counterconditioning stimuli are presented to offset fearful arousal. The choice of procedure depends on the magnitude of a dog's fear. Various techniques are employed, including play activities (tug and fetching) and romps, systematic desensitization by graduated counterconditioning or habituation, and response prevention. The most common method involves presenting a treat immediately after the noise is made, thereby training the dog to expect food whenever the gunshot occurs—an expectancy that is incompatible with fear. In some cases, the dog is prompted to sit, whereupon a sound stimulus just strong enough to capture the dog's attention is presented. The dog's attention is then immediately diverted from the event by calling its name, squeaking, and so forth. As the dog turns in the direction of the handler, a conditioned reinforcer "Good" or a click is presented and followed by food. Randomly altering the size and type of the reinforcer may help to magnify its effect, both in terms of conditioned reinforcement and the elicitation of appetitive and emotional arousal incompatible with fear.

Whenever possible during appetitive counterconditioning, the dog should be kept moving forward. Forward movement and standing are preferred to having the dog sit and wait; however, sit-stay training may be a necessary transition in the case of dogs likely to show strong escape or avoidance efforts in response to the feared stimulus. Sit-stay and down-stay training is also preferred in the case of dogs exhibiting reactive aggressive behavior in association with fear. Forward-oriented movement appears to have a functional affinity with the seeking system, mediating an increased sensitivity to signals of reward and approach, whereas remaining still or turning away or walking backward are motor correlates of the behavioral inhibition system and a heightened sensitivity (hesitation or avoidance) to signals of punishment. Lightly spraying a conditioned odor from a modified CO_2 pump just prior to the presentation of the feared sound appears to facilitate appetitive counterconditioning and reduce startle reactivity (see Miltner et al., 1994). The scent of orange (Lehrner et al., 2000) and lemon (Komori et al., 1995) appears to have some intrinsic anxiety- and stress-modulating properties that might be useful in fear control and management. A dilute lavender fragrance (Motomura, 2001), chamomile (Roberts and Williams, 1992), or vanillin (Miltner et al., 1994) may also possess intrinsic properties of value for modulating fearful arousal and adjusting acoustical startle thresholds. In the case of strong and startling sounds, timing the presentation of a diminutive sound to occur immediately before the startling event may help to reduce fearful arousal via prepulse inhibition and enhanced cognitive regulation and organized processing (see *Interrupting Behavior* in Chapter 1). Further, presenting a target-arc stimulus contiguously with the onset of the feared event may produce a potent fear-incompatible orienting response (see *Target-arc Training*). Exposure with prepulse inhibition and TAT may be particularly useful for the prevention and control of noise fears involving sensitization in association with discrete eliciting events (e.g., gunshots).

In addition to loud noises, many dogs react fearfully to unfamiliar sounds. Repeated exposure with playful encouragement and response prevention can be extremely effective in such cases. Finding a constructive way to have a fearful dog interact with the object producing the unfamiliar or startling sound can also be helpful. Many dogs exhibit fear toward motor-driven household appliances; a fear of vacuum cleaners is especially common. Since these sorts of stimuli are fairly easy to control and present in a form that allows the dog to habituate gradually, they are fairly easy to resolve, perhaps explaining the relative infrequency of such fears presenting for treatment. Shull-Selcer and Stagg (1991), for example, found that, of 30 noise-fearful dogs, 7% exhibited fear toward television or stereo sounds and only 3% presented fear related to the sound of vacuum cleaners. Some dogs exhibit persistent fears associated with the switching on of furnace relays, causing them to awake at night and pace or pant nervously. A furnace-related fear should be considered in dogs exhibiting sleep disturbances that involve pacing and other signs of fear (e.g., panting and trembling).

Fear of Sudden Movement or Change

An innate expectancy bias toward sudden movement or change appears to underlie many fears expressed toward moving objects, such as cars, bicycles, joggers, and skaters. Additive effects are likely to occur when fear-evoking stimuli are both novel and encountered in unfamiliar locations (see *Expectancy Bias* in Volume 2, Chapter 3). Consequently, initial exposure and desensitization should be carried out in familiar places and gradually extended to areas progressively less familiar to the dog. A useful method is for the owner to introduce the feared object or activity as part of a play activity. For example, a ball can be thrown in the vicinity of a bike resting against a tree. Gradually, other exposure elements are added (someone standing with a bike, rolling it, running with it, and so forth) together with various counterconditioning efforts as necessary to reduce fearful arousal. Typically, the dog is prompted to sit in the presence of the fear-evoking stimulus, starting at a distance where the stimulus elicits an orienting response but does not elicit fear. With

repeated exposures, the size and type of the food reward given to the dog should be varied to maximize positive-prediction-error effects. Dogs that are fearful of bicyclists or joggers can be introduced to the feared stimulus through fear-graded interactive exposures. For example, close interaction with a bicyclist helper can be accomplished by first having him or her stand next to the bike, followed by a walk in which the bike is rolled along next to the dog. If the dog tolerates this level of exposure, the next step can involve having the rider mount the bike and ride slowly nearby. Finally, the bicyclist is instructed to ride by in a progressively more natural manner. During these various exposure exercises, the dog should be kept under control by heeling, sitting, or staying at the owner's side. A variety of food treats can be given in varying amounts to facilitate counterconditioning and shaping objectives. Repeatedly capturing the dog's attention with a squeaker and click at the earliest sign of incipient arousal and redirecting its behavior into more constructive action (e.g., sitting or standing quietly in place) in the presence of the feared object can help counter established escape/avoidance behavior.

Some dogs exhibit a global panic or generalized anxiety whenever taken outdoors, behavior that parallels symptoms reported by human agoraphobics. Low behavioral thresholds for fear may persist despite patient environmental exposure efforts. Such fear may develop without the involvement of any identifiable aversive event in the dog's history. An innate dread of loud sounds (e.g., gunshots or thunder) and abrupt movement is sometimes evident in such dogs from a very early age or may appear spontaneously as such dogs mature. Fears and phobias associated with an innate predisposition may be controlled to some extent with behavioral and environmental management, but cure is not likely in these cases. Dogs exhibiting signs of global anxiety and fear should be referred for veterinary evaluation and possible treatment with appropriate medications (e.g., SSRIs) prior to the initiation of behavior therapy and training.

FEAR OF HEIGHTS

Many puppies exhibit a fear of heights when placed on a table or prompted to engage in some activity that poses a risk of falling, such as walking over a log bridge. The fear of heights, like other innate fears with phylogenetic origins, may be easily potentiated by pain associated with falling, making them prone to one-trial learning. For example, children may accidentally drop a puppy that they have picked up or frightened with awkward and insensitive handling. Another common fear associated with heights involves stair-climbing inhibitions, although such fears are probably more related to a competency deficit than a fear of heights. Such fear is particularly common in adult dogs that have not had adequate experience climbing and descending stairs. Some dogs will develop an aversion toward stair climbing or jumping in a vehicle as the result of bone- and joint-related problems, making a veterinary examination an important preliminary, especially in cases where fear or competency do not appear to be significant factors.

Intense fear is commonly associated with the acquisition of complex motor skills needed to interact safely with threatening situations. Mastering stairs is a good example of such habit learning involving a fear of heights. When first learning to climb steps, puppies are awkward and hesitant in their movements. In addition, they may show significant fearful arousal and freezing behavior. Alternately, they may race down the steps in a mad dash to escape the situation. As the result of practice, however, the motor skills needed to climb steps are gradually acquired, making their efforts progressively more natural and effortless. To some extent, a puppy's climbing behavior is reinforced by the relief and relaxation it gets as it successfully reaches the top of the steps. Gradually, the initial fear of heights is overcome by the development of skillful climbing and improved confidence. Learning to climb steps exemplifies the importance of competent control and skill to overcome certain natural fears.

Puppies are usually taught to climb stair steps by placing them on the uppermost step and luring them with treats and encouragement. As the necessary skills and confidence improve, more steps are added until the puppy can climb all of them at once. After learning how to climb up the stairs, the same general procedure is used to teach puppies to

climb down. Confidence building by vocal encouragement and treats play an important role in such training and should be given to puppies following every successful trial. Successful climbing is associated with significant emotional relief and relaxation, effects that may gradually help to countercondition a puppy's initial fearful reaction to steps as well as provide a source of reinforcement for climbing behavior. During the training process, the puppy should be kept on a leash to provide physical support and prevent it from falling down the steps.

As puppies learn to maneuver themselves successfully on stairs, they become progressively relaxed and confident—fearless—when climbing steps. However, dogs not exposed to stair climbing as puppies, or dogs that have been traumatized as the result of falling down steps, may prove to be much more difficult to train by using methods based on the foregoing procedure. Inexperienced dogs may resist climbing steps even after many hours of conscientious desensitization and behavioral shaping. Misguided efforts to compel them to climb by withholding meals (sometimes for days) until they finally climb the steps to get food are usually ineffective and should be avoided. Adult dogs that are afraid of steps can benefit from playful exposure to jumping over things while on outdoor excursions, climbing inclined surfaces, walking along a curb, and repeatedly stepping up and down from a low curb. Such fearful dogs may be more willing to climb low steps (e.g., the long sort sometimes found in front of schools and office buildings) when the steps are approached at an angle and then progressively approached more directly. The process involves playful and gradual exposure to progressively more difficult step-climbing challenges.

The stairs may be altered to make them easier for the dog to climb. Borchelt (1997) has suggested laying bricks side by side in front of the stairs to make the first step easier to take. Alternatively, a length of carpeting can be attached to the first few steps and extend several feet in front of the steps to provide the dog with a secure traction and "runway" up to the steps. Finally, the steps may be made less threatening to climb by covering them with a nonslip rubber runner or carpeting. Letting inhibited dogs observe a more confident dog climb steps may help facilitate a greater willingness to climb.

Given that such efforts have been attempted without success, directive exposure might be considered. In this case, the dog is physically prompting to climb by being hauled up and down the stair steps on a leash. In some cases, a wide harness can be used to support some of its weight. If a harness is used, a second leash should be attached to a strap collar for safety and enhanced control. The inhibited dog is repeatedly prompted to climb steps until relaxed compliance and enthusiastic climbing replace its resistance. Dividing the training objective into simple steps facilitates directive exposure. Initially, the dog may be prompted to climb two or three steps before being permitted to turn and climb back down again. If the dog is unwilling to climb back down, it is directed to do so with steady pressure on the leash. From the top of the steps, the dog is first prompted to climb down two or three steps before allowing it to turn and scamper back up. The opportunity to reverse directions and climb back down or up again may provide a significant source of skill and confidence building.

After a series of introductory trials, the dog is carefully hauled up and down the steps. Avoidance or resistance is consistently countered with enough leash pressure to break the dog's resistance and keep it moving. The dog's willingness to follow is reinforced with enthusiastic praise and encouragement by a helper (the owner) waiting at the top or bottom of the steps. It is imperative that the trainer does not hesitate or yield to the dog's sometimes-considerable resistance, but to drive headlong up or down the steps without taking notice of the dog's reluctance to follow. Once the dog is following the handler's lead, the directive prompt is faded and a controlling discriminative signal is added to the routine. The step-climbing behavior is repeatedly prompted over a session until the dog climbs steps with minimum prompting. With the conclusion of each successful trial, the dog is given 15 to 20 seconds of encouraging praise, petting, and treats. After a session of repeated trials, the dog is prompted into a down at the top of the steps and encouraged to relax with petting and massage for 2 to 3 minutes. The

successful session is followed by vigorous ball play.

Another common fear related to falling is associated with slippery flooring. Dogs exhibiting this fear may freeze when prompted to walk across waxed linoleum or wooden floors. When compelled to walk, they may move in a very awkward and poorly coordinated way. These problems are usually approached on two fronts. First, a carpet or vinyl runner is laid down to provide a safe pathway with good footing and traction. Second, the dog is walked over a piece of the runner in other parts of the house until the fear is not exhibited. In addition, the dog is prompted to lie down, sit, stand, and stay at various points on the runner. Next, a length of runner material is laid down starting in a separate room and crossing into the room containing the feared flooring. Treats can be put on the runner for the dog to pick up and eat, though most dogs exhibiting this type of fear may not be attracted to the food. Efforts to escape the situation are blocked, and the dog is prompted to move forward by leash and encouragement. Once the inhibition begins to break down, several passes are made having the dog move both into and out of the room. Rewarding objects and activities should be made contingent on the dog crossing the feared area. For example, the dog's meals, toys, and opportunities to go outside should all be preceded by its walking across the runner. The runner is gradually pulled back little by little over several days, requiring that the dog walk on more and more of the feared surface. Trimming nails back and treating the dog's paws with products to reduce slipping may be helpful in making stair climbing and walking on smooth surfaces easier for some dogs.

FEAR OF WATER

The psychological opposite of fear is confidence and relaxation—not appetitive arousal. Relaxation is a symptom or by-product of confidence. Without confidence, a dog simply cannot feel relaxed when faced with a potentially dangerous situation. The systematic training of skills needed by dogs to control feared situations competently serves to enhance their confidence while simultaneously reducing its fear (Figure 3.6). Coping adaptively with fear entails that a dog learn how to control the fear-evoking situation (see *Efficacy Expectancies* in Volume 2, Chapter 3). Fearful dogs often appear to be tense and worried about their ability to perform a feared activity or to control a potentially dangerous situation, rather than being especially fearful of the object or situation itself. In contrast, nonfearful dogs exhibit a more relaxed and confident attitude toward such situations as the result of a history of competent interaction and success. Many persistent fear conditions are the result of dogs not knowing what to do or not possessing sufficient skills and confidence (practice) to do what they need to do to control potentially dangerous situations. For example, many dogs are fearful of water and may refuse to go into it even when in the company of other dogs who enjoy water (positive models). Other dogs may not only lack the necessary skills to control a feared situation, but may actively fear stimuli associated with it. For example, some dogs are so fright-

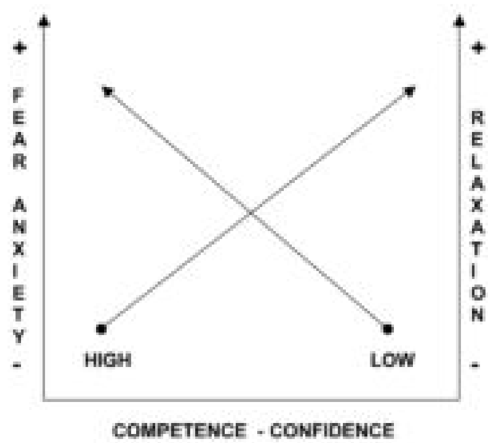

FIG. 3.6. Relaxation is a natural corollary of competence. As a dog's competence and confidence increase, fear is generally reduced as relaxation increases. Relaxation competes with the tenseness, worry, and vigilance associated with anxious and fearful states. The elation and relaxation associated with competent control over a potentially dangerous situation represent a powerful counterconditioning influence and source of positive reinforcement for dogs.

ened of water that they frantically scurry away from puddles to avoid coming into contact with it. In the case of some storm-phobic dogs, a single drop of rain can precipitate a major fearful episode.

Interactive exposure to water can be highly effective in the treatment of such phobias. Performing a variety of obedience exercises reinforced with food, play, and affection while near water is often beneficial. Gradually, the dog is progressively moved closer to the water until it is directed to walk into it or stay while standing in it. Once accepting the feel of water, stronger incentives, like an opportunity to play tug or fetch, are introduced near it. The play activity is gradually moved closer to the water until the dog is able to fetch things thrown into it. Walking at heel or fetching a ball while in water invariably teaches a dog many skills about interacting with water that can help improve its general confidence and attitude toward water. Probably the best way to prevent and overcome a fear of water is to train a dog how to swim.

Fear of Riding in Cars

The majority of dogs seem to look forward to car rides. However, some dogs, especially those that have not been exposed to car rides early in life (see *Habituation, Sensitization, and Preventive-exposure Training*), may be quite uneasy or fearful while in a car. The first step is to familiarize the dog gradually with the car. With car doors open, the dog is simply walked around the car, perhaps performing various obedience exercises or encouraged to play (e.g., tug or fetch) when near it. Any approach toward the car can be bridged ("Good" or click) and reinforced. Bonuses involving highly appetizing food items can be given in a pan that is placed progressively closer to the car. In some cases, the dog is tied to a tie-out that is attached to the car. At such times, the dog can be given a highly desirable chew item (e.g., rolled rawhide or a beef bone), and the car radio can be turned on. Graded interactive exposure and counterconditioning proceed through progressive steps until the dog willingly approaches the car. PFR training with an odorant signature can be very helpful. The conditioned scent is applied to the inside of open doors and at various other places on the outside of the car. Since the dog is highly motivated with approach incentives during homecomings, it may be useful to arrange for someone to let the dog out of the house at such times in order for it meet the owner at or in the car. At such times, the owner should get in the rear of the car and slide across the seat, giving the dog room to jump in. The excitement elicited by the owner's homecoming may offset fearful avoidance and increase the dog's confidence. As the owner gets out of the car, both doors should be left open. Depending on the dog's response, the owner might opt to get back inside the car and encourage the dog to follow. As the dog's willingness to jump into the car improves, the owner should prompt the dog to get in first. Over several trials, a progressively more natural pattern is introduced in gradual steps and reinforced. Feeding the dog by hand or putting food on the car seats and floor may encourage the dog to move about, explore the situation, and become progressively comfortable. At the conclusion of the session, the dog is given a brief period of ball play or a walk. Another alternative is to allow the inhibited dog to play with a more confident dog close to the car with both back doors open. The confident dog can be encouraged to jump into the car to get food previously thrown there and the reluctant dog encouraged to follow. In addition, a ball or other toy can be thrown into the car, perhaps causing the reluctant dog to jump in after it. Holding the reluctant dog back for 15 seconds or so may help to build a heightened enthusiasm to follow the confident dog into the car.

An unwillingness to get into a car may be related to a lack of confidence, stemming from inadequate training. Some dogs may refuse to get into a car, as though afraid of it, but once inside not show any significant signs of anxiety or fear. In such cases, various training efforts should be carried out to teach the inhibited dog how to jump in and out of the car. As in the case of stair-climbing inhibitions, a dog that strongly resists jumping into the car may benefit from directive exposure. In this case, the dog is repeatedly prompted to jump up into the car. Any resistance is consistently countered with sufficient force to compel the dog to jump. As the dog leaps

into the car, relief is associated with vocal encouragement, food, and petting. After 15 to 20 seconds, the dog is directed out of the car, and the procedure is repeated. Each trial is repeated in the same manner until the dog jumps up on its own. Once the dog is responding, a vocal cue such as "Hup" can be paired with the action of jumping into the car. At the end of the training session, the owner and the dog should remain in the car for 2 to 3 minutes, thereby obtaining benefits associated with opponent-relaxation effects. This period is associated with quiet petting, massage, listening to the car radio, and the presentation of an olfactory safety cue.

Dogs may develop fears about riding in the car as the result of traumatic events or a history of aversive consequences associated with car trips. For example, dogs that are taken in the car only for veterinary visits, especially if they have experienced painful procedures, may develop an anticipatory fear associated with car rides. When such causes are suspected, frequent rides that result in more attractive outcomes (going to the park, picking up children at school, and so forth) can help to counteract such fears. Some dogs who have been exposed to an automobile accident or abrupt stop throwing them around inside the car may develop a lasting fear that makes them uncomfortable in cars. The affected dog may pace back and forth, pant, whine, and in general appear to be unable to settle down. Such dogs may be aroused continuously during drives or become aroused only after a sharp turn or bump in the road. One advantage of this class of fears is that the duration of exposure can be controlled, making response-prevention procedures feasible. Smooth and straight rides(e.g., on expressways) can be taken during which the dog is appropriately restrained from moving about. In addition, the dog should be taught to sit and stay while in the car. As the dog shows signs of calming, the car can be pulled over and the dog taken for a walk.

FEAR OF ENCLOSED SPACES AND CONFINEMENT

Many puppies initially respond to crate confinement with intense fear and escape behavior. In an important sense, crate confinement is more like a trap than a den. Under natural conditions, a situation like a crate would be a serious threat to an animal. It is little wonder, therefore, that many puppies and dogs respond with intense aversion and distress when locked inside a crate for the first time. Unfortunately, many new dog owners simply put the puppy in a crate and leave it there to work through its distress alone, with little appreciation for the potential harm done by such treatment. The puppy may subsequently eliminate in the crate as the result of ensuing distress or because the owner may neglect to take it out on a timely basis, thereby making an already problematic situation much worse. Puppies that eliminate in the crate may be further stressed by abusive after-the-fact punishment and water deprivation initiated to correct the elimination problem. Because of work and school schedules, the puppy may spend the vast majority of the day in a crate. Thus, life goes by with the puppy rapidly transitioning through extremely sensitive and influential developmental periods under the adverse and deprived conditions associated with excessive crate confinement and unsympathetic rearing practices. The net result of such treatment is sustained and inescapable stress, perhaps quietly sensitizing neuroendocrine systems in ways that may make the puppy vulnerable to develop serious adjustment problems in adulthood. As a result of such risks, crate confinement should be introduced through gradual steps involving desensitization by counterconditioning and associated with compensatory measures to offset stress associated with its use (see *Crate Training* in Chapter 2). Although gradual exposure is much better and likely to result in fewer adverse side effects, crate confinement should still be used with a proper degree of concern for potential harm. Crate confinement should be used in a limited way for specific purposes of space management and training, but not as permanent way of life (see *Adverse Effects of Excessive Confinement* in Chapter 2).

In the case of adult dogs, many show a persistent aversion toward crate confinement in association with various adjustment problems, including separation distress and fears (e.g., storm phobias). Such problems need to

be addressed and ameliorated first in order to effectively modify the dog's adverse response to confinement. In the absence of contributing adjustment problems, dogs exhibiting a strong aversion to crate confinement are usually responsive to some combination of graded interactive exposure with RP-CC and shaping. For example, the dog is trained to obtain food by approaching the front of the crate. Initially, treats are dropped on the floor just in front of the crate and then gradually tossed inside of it. Some dogs appear to be afraid of the crate pan and the noise it makes as they step on it. Temporarily, removing it or laying down a blanket or rug can be very helpful in such cases. To encourage more willingness to approach the crate, a standard shaping procedure can be used to reinforce successive approximations, with the food reward being delivered closer and closer to the crate opening. In addition to such training activities, the dog should learn to find highly desirable treats and chew toys in or around the crate. Also, the dog can be fed with its bowl placed close to the crate and then in it. Once the dog is approaching the crate and entering, it is trained to wait briefly before being let out again. With progress, the gate of the crate can briefly closed and opened again to reward the dog's behavior (see *Guidelines for Successful Crate Training: Step 3* in Chapter 2).

Social Fears and Inhibitions

Social and environmental fears may be influenced by different emotional mechanisms and systems. The fear of others and the fear of unfamiliar objects are differentiated at an early age under the influence of socialization and habituation. Social and environmental fears appear to modulate or inhibit the expression of one another, suggesting that such fears are not under the control of a unitary substrate. For example, MacDonald (1983) found that a fear of unfamiliar objects and the fear of people are not summative; on the contrary, a reciprocal inverse relationship appears to influence their expression such that wolf pups afraid of unfamiliar objects tend to be less afraid of people, whereas wolf pups afraid of people tend to be less afraid of unfamiliar objects. These findings suggest the possibility that the fear of unfamiliar environmental events tends to promote social affiliation (excessive dependence), whereas increased social fears may tend to increase independent environmental exploration and problem-solving activities (enhanced independence).

Toward People

Dogs commonly present with varying degrees of fear toward strangers. The most common causes underlying excessive social fear and reactive behavior involve some constellation of genetic predisposition, socialization deficits, or traumatic exposure or learning. A number of techniques have proven effective in reducing social fears. Woolpy and Ginsburg (1967) have described the basic pattern of change that occurs during the treatment of excessive social fear in wolves. These stages include escape efforts, followed by avoidance, approach with aggression and, finally, friendly social interaction. It is interesting to note that, as escape and avoidance give way to approach behavior, an increased risk of aggression was observed to occur. This is consistent with the notion that fear exercises an inhibitory influence over aggression. In the case of highly aggressive animals, fear reduction may have a potential collateral effect of increasing social assertiveness.

The most beneficial techniques used for the management of social fear involve some combination of graded interactive exposure, counterconditioning, relaxation, modeling, response prevention, and play. These various procedures facilitate social contact, which serves to disconfirm aversive expectations and encourage more constructive social behavior. Deciding which procedure or combination of procedures to employ depends on the nature of the problem. Perhaps, the most common training pattern used to alter social inhibition and avoidant behavior is to train dogs to sit and accept food in the presence of people under a variety of evocative situations. As the dog's fear is reduced, closer and closer contact and interaction may be attempted. Social fears such as those directed toward visitors and other brief encounters may be facilitated by

the length of exposures being insufficient to result in relaxation. Typically, persons who are not feared by the dog are those that have spent extended time interacting with the dog during visits. Going for long walks together with an unfamiliar person (a pet walker can be hired for this purpose) can be extremely helpful. The walks must be long enough to habituate fearful responding. Once the dog is showing signs of reduced fear and increased interest in obtaining social contact (food and affection), activities like ball play can be explored as a means to extend socialization efforts. Nebuhr and associates (1977) reported a case involving an "extremely shy and withdrawn" German shepherd that was exposed to interactive play activities as the primary therapy modality. After 2 weeks of patient play therapy, the owner reported dramatic improvement in the dog's behavior, indicating that the dog had become progressively relaxed and "acted like a normal dog" (11).

The use of play in such cases should be considered only after successful exposure efforts. Of course, challenging an overly fearful/aggressive dog to play with an unfamiliar person would be dangerous and not be very productive. Dogs that are unwilling to play treat social contacts as aversive events. Another possibility is that socially inhibited dogs may lack the necessary skills and confidence needed to play. As already discussed, encouraging a fearful dog to play can promote a more trusting and open attitude toward social interaction. In the case of mild social inhibitions, play (especially in puppies) can be initiated as a starting point, but only if the risk of aggression is negligible. It should be emphasized that not all dogs that show a disinterest in play are fearful; often such dogs are unresponsive because of underlying social irritability or aggressive tensions. *Prompting such dogs to play may evoke aggression.* Dogs exhibiting social aggression with fear should be appropriately restrained with a muzzle-clamping head halter or muzzle, as needed for secure control.

Graduated counterconditioning and interactive exposure can be staged in places where high levels of foot traffic can be found. City parks can be useful for this. Relaxed exposure can take place as the owner sits on a bench with the dog on a limited-slip or halter collar, depending on need. During outdoor exposure, a hip-hitch and control lead can be extremely useful for maintaining control while freeing up the hands to deliver petting and massage, squeaks and clicks, food treats, and so forth. As passersby approach, the dog can be prompted to sit, thereby obtaining various social and tangible rewards. The delivery of noncontingent rewards (priming) or rewards delivered on a DRO schedule can be very useful. During DRO training, a brief period (e.g., every 10 to 20 seconds) is set at the end of which the dog is rewarded, provided that it does not exhibit avoidance behavior during the period. Over a number of trials, a variety of prosocial behaviors will be adventitiously reinforced. In some cases, a more sustained source of appetitive stimulation may be needed. For such purposes, a large syringe can be filled with a soft delicious food reward that is slowly dispensed to the dog in a drip, blob, or continuous squeeze, depending on need. Cheese from compressed cans can be dispensed in a similar way. Finally, a licking stick, consisting of a spoon or wooden stick slathered with peanut butter, can be a convenient way to deliver a sustained reinforcer while walking a dog. Since appetitive arousal is incompatible with fear, such a procedure can be very useful for calming a dog. Attention-control exercises can also be practiced intermittently, requiring that the dog turn and focus its attention on the trainer before the reward is delivered. Training a dog to turn its attention toward the trainer at such times gives it a potential coping strategy when confronted with fear-evoking social situations. Dogs trained in this way quickly learn to look toward the trainer for support and guidance. This procedure is especially effective if the amount and type of reward are varied and attention is paired with a conditioned reinforcer. In one variation, a novel odorant is injected into a squeaker toy (e.g., a ball) that is used as a conditioned reinforcer. As a result of repeatedly pairing the scent with food and behavioral success, eventually a very potent conditioned emotional effect is produced. Together with other conditioned stimuli, the conditioned odorant can be used to help restrain aversive emotional arousal associated

with fear-evoking situations. Dogs that exhibit a strong interest in play may be encouraged to play tug or fetch a ball while on leash in order to facilitate a more relaxed attitude in unfamiliar surroundings. Training efforts can also be carried out near stores, where exiting shoppers provide discrete and repeated trials for approach exposure. During such exposure training, the dog can be prompted to sit and stay as the shopper comes through the store exit.

Dogs that fear strangers are often very reactive around crowds. Exposure to groups of people should proceed very gradually, beginning with minimally provocative situations and only slowly advancing toward more challenging situations according to the dog's ability and tolerance. In the case of a moderate fear of crowds, a graded interactive exposure technique may be used. Intensive attention training as well as shaping of controlled walking and heeling skills can be performed. Every few steps with the dog in the controlled-walking position, the trainer clicks and delivers a variable reward. In addition, the dog should be prompted to quick-sit every so often after bridging controlled walking. In this case, instead of giving the dog a food reward, the vocal and hand sit signal are delivered, followed by "Good" and the delivery of a food reward. During an outdoor event, for example, where a large crowd is gathered, the dog may react with less fear if it is initially walked along the opposite sidewalk away from the gathering. After 15 or 20 minutes, provided the dog is not showing any overt signs of anxiety, it can be led across the street and walked along the adjoining sidewalk, but still kept away from direct contact with people. Finally, after another lengthy period of exposure, and provided that overt signs of fear are absent, the dog may accept more close contact and interaction with the fringes of the crowd, and so on. Incidentally, since walking is mildly anxiety reducing, it is helpful to keep the dog moving during such exposures.

Dogs exhibiting fears toward people should receive intensive basic training as a preliminary to graduated counterconditioning and response-prevention therapy. Most fearful dogs develop increased confidence, improved attention abilities, and enhanced control over emotional behavior as the result of daily structured training activities. Sit-stay and down-stay training using a reward-based process in conjunction with attention and orienting conditioning can be very useful to promote control and fear-antagonizing internal states linked with sitting and lying down. Also, PFR training with olfactory conditioning can be useful. Once an odorant is conditioned, it can be placed on a tissue and held in the trainer's hand or dispensed with a squeaker or modified CO_2 pump. Delivering the scent during social encounters appears to help modulate a dog's emotional arousal, perhaps making social counterconditioning efforts more effective. These various preliminary attention and basic training procedures are collectively referred to as the *counterconditioning platform*.

Toward Dogs

Learning to interact confidently with other dogs begins early in a puppy's life, especially between weeks 3 and 8. Puppies that are taken too early from their littermates and mother, or otherwise inadequately socialized, may exhibit signs of increased fearfulness around dogs as they reach maturity. Undersocialized dogs may exhibit pronounced deficits in their ability to reciprocate playful overtures initiated by other dogs. They are often unable to exchange ritualized threat and appeasement displays competently and may be particularly awkward in situations involving unfamiliar dogs. The friendly approach of another dog may evoke frantic efforts to escape or cause the overly fearful dog to freeze in a trembling ball of nerves. Typically, dogs exhibiting a socialization deficit may feel equally uncomfortable in the presence of both male and female dogs, but some may show specific aversions and preferences. In addition to socialization deficits, fear of other dogs can often be traced to traumatic experiences occurring at some point in the dog's life. Young puppies are especially prone to develop persistent fears after being attacked by an adult dog. Such experiences may be especially traumatic in cases where the event occurs in an unfamiliar location or in a location already associated with distress, e.g., a veterinary clinic or kennel.

The aforementioned procedures for managing dogs fearful of unfamiliar people are modified for controlling fear of other dogs. Socialization and training efforts should be carried out that bring the socially inhibited dog into progressively more demanding encounters with other dogs. A good controlled situation for such exposure is a veterinary clinic during office hours. Dogs entering or leaving the clinic provide discrete trials of controlled exposure. As dogs exit the clinic, the trainer can prompt the dog's attention (squeak and click), signal it to sit, and reward it ("Good") with a variable treat, first at a distance and then progressively closer to the target dog. The presence of a friendly and nonthreatening canine model can also be very helpful. Using a friendly dog model to go along on walks and to participate in training sessions may provide a framework for making more positive future contacts with other dogs. The positive model may also help the dog to overcome some of its inhibition. Once some degree of control is established, the fearful dog can be taken to group training classes for additional exposure and counterconditioning.

Separation Distress and Panic

PART 1: NEUROBIOLOGY AND ONTOGENETIC INFLUENCES

The dog's ability to form satisfying attachments and bonds with people has secured for it a unique place in human society. Dogs are often treated as members of the family, with a level of care and affection that rivals the treatment reserved for children. For most people, the relationship formed with a dog is immensely gratifying. The majority of dogs appear to reciprocate our affection and invite close contact. Most dogs are adept at engaging people in prosocial relations by attracting attention to themselves by various means. In fact, much of what well-socialized dogs do appears calculated to maintain or enhance close contact with human companions. In addition to making bodily contact, various gestures, postures, vocalizations, and expressive rituals are used to communicate the dog's prosocial intention to interact and make contact with us. The preeminent means for promoting affiliative contact is play. Through our

mutual capacities to play, people and dogs seem to transcend evolutionary barriers and open a common ground of empathy and appreciation for one another.

The powerful attraction and affiliations formed between dogs and people are a source of considerable pleasure, so long as the object of affection is present and available. When left alone, all normal dogs appear to experience some degree of discomfort by separation; however, the vast majority learn to cope with routine separation without becoming overly distressed. Many, though, respond adversely to separation, exhibiting varying degrees of despair, emotional arousal, or panic. Separation-reactive dogs may engage in a variety of undesirable behaviors, including motor excesses (pacing, running about, and jumping up on counters and window sills), excessive vocalization (persistent barking and howling), various destructive activities, and separation-related elimination problems. In extreme cases, a dog appears inconsolably worried and panicked about its inability to restore contact with the absent owner. Some dogs become separation reactive as the result of being confined to a separate room while the owner is elsewhere in the house, whereas others may exhibit signs of distress (e.g., household elimination and destructiveness) as the result of being merely denied contact and attention from the owner. Aside from the potential household damage produced by such dogs and the complaints of neighbors about excessive barking, separation-related distress represents a significant welfare concern.

Separation distress in dogs presents with a variety of behavioral signs under the influence of several coactive influences, including anxiety, fear, stress, boredom, frustration, and panic (see *Separation Distress and Coactive Influences* in Volume 1, Chapter 4).

Traditionally, borrowing from human psychiatry, the term *separation anxiety* has been adopted to name the syndrome in dogs. In the author's opinion, the notion of *anxiety* at separation has led to considerable confusion with respect to understanding the etiology of separated-related behavior and its treatment. First, separation distress appears to be mediated by a neural circuit that is functionally discrete from circuits subserving anxiety and fear. Second, although some overlap certainly exists between separation distress and anxiety, overlap also exists with other coactive influences, such as boredom, frustration, stress, and panic. As a result of these considerations, the term *separation distress syndrome* (SDS) has been adopted to emphasie the multimodal function of behavior commonly referred to as separation anxiety.

NEUROBIOLOGICAL SUBSTRATES OF ATTACHMENT AND SEPARATION DISTRESS

Adaptive behavior is the outward appearance of an utterly astonishing and complex infrastructure of physiological processes. Understanding the evolutionary origins and biological significance of canine social behavior, attachment, and separation distress depends on some familiarity with neurobiology and the neural substrates mediating the expression of such behavior. Dogs, like other mammalian species, have evolved species-typical behavior patterns associated with maternal care (nursing), separation calls, and play. MacLean (1985) has implicated paleomammlian limbic pathways and diverse interconnections between the amygdala, hippocampus, septum, thalamus, hypothalamus, and cingulate cortex as providing the neurobiological substrates for the emergence of the mammalian capacity to give and receive care, to seek and enjoy company, and to interact playfully (see *Neurobiology of Attachment and Separation Distress* in Volume 1, Chapter 3).

Neuropeptides and Social Behavior

Humans and dogs exhibit a mutual need for social contact and comfort, providing a motivational basis for interspecies attraction and social bonding. Odendaal (2000) refers to our shared need for positive social interaction as emanating from an emotional capacity, *attentionis egens*, to give and receive affection and comfort from the company of one another—a capacity that is evident in social behavior as well as reflected in a variety of physiological changes that occur during such interaction (see *Tactile Stimulation and Adaptation* in Chapter 6). A diverse assortment of neuro-

chemical influences mediates social attraction and affiliative behavior. For example, phenylethylamine, a centrally active amine, is believed to promote a rapid increase in alertness, activity, and positive affect (euphoria), changes that may be involved in the biology of social attraction between people and dogs. Both people and dogs show a significant increase in phenylethylamine activity, as indicated by increased levels of circulating phenylacetic acid (a metabolite of phenylethylamine) following brief periods of positive social interaction (Odendaal and Lehman, 2000).

A variety of neuropeptides that are strategically distributed throughout the paleomammalian system serve to mediate the expression of attachment, separation distress, social comfort, and a variety of other ancient social behaviors. These neuropeptides include endogenous opioids (endorphins and enkephalins), substance P, oxytocin, prolactin, and arginine vasopressin (AVP). A number of different opioid receptors are widely distributed in the canine brain, with many concentrated in areas of the brain believed to mediate the expression of separation distress and agitated-explosive behavior (panic circuit) (Panksepp, 1982). These opioid-sensitive receptors serve a number of functions, including the modulation of physical and emotional pain, the regulation of mood, the mediation of reward and pleasure, and social attachment (see *Limbic Opioid Circuitry and the Mediation of Social Comfort and Distress* in Volume 1, Chapter 3). Opioids have been shown to modulate canine social behavior (Panksepp et al., 1983; Knowles et al., 1989) and separation-distress vocalization (Panksepp et al., 1980). Opioidergic disturbances have been implicated in the elaboration of various mood and emotional deficits associated with learned helplessness and depression (Tejedor-Real et al., 1995).

The neuropeptide substance P closely interacts with opioid pathways in various parts of the brain, but in association with opposite hedonic effects. The activation of substance P pathways is closely associated with psychological stress and the experience of emotional anguish and pain. Substance P exhibits a preferential affinity for the receptor neurokinin 1 (NK-1). NK-1 receptors are concentrated in brain areas associated with aversive emotional arousal (e.g., the amygdala, hypothalamus, and periaqueductal gray). In addition to mediating anger and rage, substance P plays a role in the transmission of peripheral pain, mediates separation distress, and facilitates the addictive effects of opiates. Murtra and colleagues (2000) have reported that NK-1 knockout mice (mice lacking the gene needed for the expression of the NK-1 receptor) are unresponsive to morphine and do not show physical withdrawal symptoms when the administration of the drug is stopped. Substance P agonists generate separation-like distress vocalizations in guinea pigs—an effect that is "virtually abolished" by pretreatment with a substance P antagonist. Substance P antagonists have been shown to suppress separation-induced distress vocalization completely in guinea pigs (Kramer et al., 1998).

Another highly influential neuropeptide that closely interacts with opioid pathways is oxytocin, perhaps co-mediating emotional changes opposite to those produced by substance P. Whereas substance P is evocative of emotional anguish, social irritability, and rage, oxytocin promotes emotional comfort, pleasure, and well-being, as well as exerting potent antiaggression effects (Panksepp, 1998). In addition to mediating such biological functions as parturient contractions and the milk let-down reflex, oxytocin is involved in the expression of maternal behavior, social bonding, and the modulation of separation distress (see *Social Comfort Seeking and Distress* in Volume 2, Chapter 4). Oxytocin has been identified as playing a significant role in early olfactory learning, especially the rapid conditioning of environmental-scent stimuli associated with the mother (Nelson and Panksepp, 1996) and place attachments. Such learning may mediate the calming effects that familiar and safe places have for dogs. Place attachments associated with the mother's odor may prevent the young from wandering too far away from the nest and the mother's protection, as well as promote huddling behavior. In contrast to the formative effects of oxytocin on place attachments, substance P and substance P agonists appear to induce strong place aversions (Kramer et al., 1998).

In addition to olfactory memories associated with place attachments, oxytocin promotes the consolidation of olfactory memories needed for social recognition (Ferguson et al., 2002). In rats, the effect of oxytocin on social recognition appears to be dose dependent, with low doses facilitating social recognition learning and high doses blocking it. Knockout mice lacking the gene necessary for the production of oxytocin exhibit various social deficits, including an inability to effectively process olfactory social stimuli and to consolidate olfactory memories of conspecifics (Ferguson et al., 2000). Interestingly, these olfactory-dependent social recognition abilities are restored by the injection of oxytocin into the medial amygdala (Winslow and Insel, 2002). Knockout mice are also more aggressive as adults than oxytocin-expressing counterparts (Winslow et al., 2000). Although not yet scientifically demonstrated to my knowledge, oxytocin probably plays a central role in mediating long-term kin recognition in dogs (see *Attachment and Separation Distress* in Volume 2, Chapter 4).

Developmental Adversity and Adjustment

Affiliative behaviors and separation-distress behaviors are grounded in both phylogenetic and ontogenetic influences. Developmental influences on dog behavior take place within the context of biological constraints and timetables that roughly serve to define a dog's potentiality—a biogenetic potential that remains unactualized in the absence of appropriate experience and organizing learning. A sensitive period for socialization occurs during a time of rapid change and development early in a puppy's life. The socialization period is characterized by an inverse relationship between waning social attraction and a gradual increase in social aversion and fear (Figure 4.1). In addition to the expression of biogenetic propensities for social contact, attachment, and aversion, acquired Pavlovian expectancies and instrumental social and motor skills gradually shape the behavioral phenotype to reflect social and environmental pressures. Each step in the process necessarily influences subsequent steps (epigenesis), with disruption occurring at any point in the process potentially exerting pervasive disturbances over subsequent developmental organization and behavior.

Learning consists of various sensory and neurobiological processes whereby information and behavior are integrated and coordinated with the ultimate goal of optimizing an animal's ability to adapt and achieve a better state of being. The ability to learn and adjust enables dogs to predict and control the social and physical environment better. However, the adaptation process is not without error, adversity, and misfortune—life is relentlessly stressful and risky. Consequently, evolution has favored the perpetuation of biobehavioral stress systems that are flexible and capable of coping under the adversities of behavioral conflict, failure, and threats (e.g., fear, anxiety, frustration, anger, and irritability). Biological stress serves to mobilize a cascade of coordinated behavioral and physiological events that improve an animal's ability to survive under adverse conditions. However, as the result of disruptive early experiences or trauma, these adaptive mechanisms may become maladaptive and potentially result in lifelong disturbances in a dog's ability to cope and respond adaptively to stressful situations, especially those stressors involving emotional adversity.

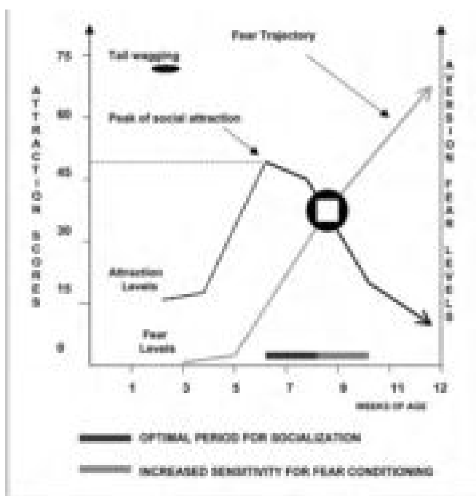

FIG. 4.1 The socialization period is associated with numerous developmental changes reflected in dramatic shifts in social attraction and fear.

During the first 16 weeks, various changes in autonomic reactivity and the propensity for social attraction and aversion follow a consistent pattern of heart-rate changes (Scott, 1958) (see *Socialization: Learning to Relate and Communicate* in Volume 1, Chapter 2). Until the onset of the socialization period, neonatal puppies exhibit a rapid heart rate before it undergoes a significant deceleration between weeks 3 and 5, possibly associated with the emergence of parasympathetic dominance—an autonomic change occurring in close association with increased social attraction and elevated thresholds for fear. After week 5, a puppy's heart rate begins to accelerate again and peaks between weeks 7 and 8, marking the emergence of sympathetic dominance. With the onset of sympathetic dominance, puppies become progressively wary about making new social contacts and begin to show increasing fear and responsiveness to aversive conditioning, especially between weeks 8 and 10. Fear thresholds continue to fall until the close of the socialization period at week 12. From weeks 7 to 16, the heart rate progressively levels out toward adult levels, representing a period of autonomic equilibrium (Figure 4.2). During periods of autonomic and developmental change, puppies may be particularly vulnerable to traumatic conditioning and stress. Early traumatic events that increase sympathetic activity may significantly impair a puppy's ability to cope with stress and aversive stimulation as an adult, making the dog either hyperresponsive (choleric/c type) or hyporesponsive (melancholic/m type) to environmental stimulation. On the other hand, insufficient stimulation may also produce a damaging effect. The key is to provide puppies with appropriate and adequate stimulation to support their developmental needs and promote adaptive adjustments consistent with sanguine (s type) and phlegmatic (p type) typologies.

Origin of Reactive versus Adaptive Coping Styles

Traumatic stress may also exert a pronounced influence on subsequent development from a much earlier age. Deprivations and excessive stress during the first 2 weeks of life may permanently disrupt the normal pattern of neural development and result in disturbances associated with coping and impulse-control deficiencies, common features of many dog behavior problems, including separation-related problems (see *Postnatal Stimulation*). Given the potent effects of early handling and gentling on stress reactivity, emotionality, and

social dominance, it is reasonable to assume that unfavorable influences during the neonatal period may adversely impact separation-distress circuits [see *Neonatal Period (Birth to 12 Days)* in Volume 1, Chapter 2]. During the first 2 weeks of life, there is a transient "overproduction" and proliferation of oxytocin and AVP receptors in limbic brain areas of infant rats that gradually moves toward adult levels as rat pups mature (Tribollet et al., 1991). The adult distribution of AVP-binding sites is established by the time of weaning. These sites include areas associated with the mobilization of fear and emotional stress in adulthood [viz., the locus coeruleus, the nucleus of the solitary tract, the central amygdala, and the septal area (an area associated with separation distress)]. On the other hand, oxytocin sites are generally located in areas of the brain associated with social attachment, reward, and the behavioral approach system (viz., the cingulate cortex, the nucleus accumbens, and the caudate putamen). Oxytocin sites undergo change in distribution and density at the time of puberty, including a proliferation into brain areas associated with social recognition (the olfactory tubercle), social fearful behavior (the posterior central amygdala), and sexual and maternal behavior [the bed nucleus of the stria terminalis (BNST)]. By day 60, there is a twofold increase of oxytocin-binding sites expressed in the central amygdala and the BNST, another site believed to play a role in the elaboration of separation distress. Finally, oxytocin-binding sites in the ventromedial hypothalamus were expressed only toward the end of the 60-day period.

The changing distribution of oxytocin-binding sites suggests the possibility that similar changes might mediate developmental changes in puppy social approach and fear patterns described previously, suggesting several interesting hypotheses concerning a potential role of oxytocin and AVP in the organization of social behavior and the integration of social-emotional stress responses. The restraint of autonomic arousal and the mediation of social approach between weeks 3 and 5 may reflect heightened oxytocin activity, whereas the increasing fear and sensitivity to avoidance learning emerging as the puppy moves into week 8 and 10 may be due to emergent AVP dominance and the downregulation of oxytocin. In addition, although this is conjecture, early AVP activity may play a role in keeping puppies huddled together via a calming effect mediated by oxytocin produced in association with nursing and tactile stimulation with littermates, which, if discontinued by the puppy wandering too far away, might trigger distress signals via the activation of AVP and CRF painlike circuits, causing the puppy to seek contact with the mother and littermates to obtain relief via oxytocin release. In addition to mediating contact comfort, oxytocin appears to facilitate social recognition (Ferguson et al., 2002). The theme of comfort and safety seeking with familiars that is sketched out in early infancy may exert a profoundly influential effect over the epigenetic development of social behavior, attachment, and separation-related behavior. Accidental separation of a neonatal puppy over some lengthy period might result in significant sensitization of separation-distress circuits, perhaps predisposing the puppy to a heightened sensitivity to separation in adulthood. Inadvertent exposure to excessive stress or trauma in early puppyhood may play a key etiological role in the development of a variety of social and stress-related behavior problems (e.g., separation panic and owner-directed aggression).

Early epigenetic approach-withdrawal adjustments foreshadow the elaboration of increasingly sophisticated social recognition abilities, comfort- and safety-seeking behaviors, emotional complexity, and cognitive abilities that gradually unfold and enable dogs to form prediction-control expectancies and social relationships. The development of these abilities enables dogs to learn and to adapt by means of optimized control modules, modal strategies, and choice (see *Ontogeny and Reactive Behavior* in Chapter 8). As such, learning enhances a dog's ability to control social and environmental events, thereby increasing its competence and well-being, whereas a failure to learn from experience promotes incompetence, distress, and reactive behavior. The process of adaptive learning appears to be intimately linked to oxytocin and dopamine reward circuits. When eating food, dogs exhibit a rapid, steep, and extremely brief spike of oxytocin release (Uvnäs-Moberg et

al., 1985). The oxytocin spike associated with eating is sensitive to conditioning, with dogs responding to conditioned stimuli that regularly occur in advance of the presentation of food. Whereas oxytocin appears to mediate reward associated with gratification, comfort, and safety, dopamine appears to mediate reward associated with surprise, heightened arousal, and increased incentive (Schultz, 1998). These differential reward effects produced by oxytocin and dopamine point to an important function of cynopraxic training and therapy, to wit: the mediation of an antistress response via physiological and neurobiological changes conducive to social attachment and bonding. However, in addition to mobilizing an antistress response, oxytocin exerts potent anti-aggression and antifear effects while promoting social approach, affectionate interaction, and calming. Consequently, in addition to shaping and modifying behavior, petting and food rewards appear to mediate numerous additive counterconditioning and socialization benefits via the conditioned and unconditioned release of oxytocin and other neuropeptides conducive to an adaptive coping style.

Although the significance of these changes in the distribution of oxytocin-binding and AVP-binding sites remains conjectural, various suggestions have been put forth, including a role in brain growth and neural elaboration, which facilitates the formation of infant-mother attachments and the modulation of separation-related behavior. In addition to developmental changes, stressful environmental influences appear to exert pronounced effects on neuropeptide-receptor density and activity. For example, the number of oxytocin-receptor sites in the hippocampus is transiently decreased in infant rats by brief repeated exposure to maternal separation (Noonan et al., 1994).

> It is interesting to speculate that even brief separations of the infant from the mother, manipulation that involves both stressing the infant and the disruption of a social bond, may have effects on oxytocinergic activity that subsequently influence the expression of social- or stress-related behaviors or endocrine function. (119)

The developmental effects of comfort- and stress-induced alterations in oxytocin-receptor proliferation has been shown to exert profound changes in adult social and maternal behavior (see *Antistress Neurobiology, Maternal Care, and Coping Style* in Chapter 8).

Stress and Flight or Fight Reactions

The close association of AVP with areas of the brain associated with the activation of emotional stress, fear, and aggression (see *Arginine Vasopressin and Aggression* in Volume 1, Chapter 3) suggests the possibility that AVP may play a significant role in the mediation of a reactive stress response, whereas oxytocin appears to mobilize an adaptive or antistress response conducive to cooperative interaction and bonding (Uvnäs-Moberg, 1997b). The finding that the central amygdala expresses both oxytocin-binding and AVP-binding sites is intriguing with respect to this general hypothesis and the notion that these neuropeptides may mediate opposite effects on the elaboration of emotional stress responses and social adjustment. Whereas oxytocin appears to activate systems conducive to what might be called an adaptive *flirt and forbear* response (see *Adaptive Coping Styles: Play, Flirt, Forbear, and Nip* in Chapter 6), AVP appears to mediate a reactive flight or fight response (social avoidance, punishment, and agitation), perhaps via epigenetic interaction with corticotropin-releasing factor (CRF), testosterone (see *Arginine Vasopressin, Testosterone, and Serotonin* in Chapter 6), and substance P.

CRF, oxytocin, and AVP are all produced by the paraventricular nucleus (PVN) of the hypothalamus. The release of CRF by the PVN activates the hypothalamic-pituitary-adrenal (HPA) system by prompting the anterior pituitary gland to release adrenocorticotropic hormone (ATCH), which, in turn, causes the adrenal cortex to secrete glucocorticoid hormones (cortisol and corticosterone) into the bloodstream (see *Startle and Fear Circuits* in Chapter 3). Circulating glucocorticoids exert a negative-feedback effect on the hypothalamic stress response. CRF-containing neurons located in the central amygdala initiate the emotional stress response via projections to the locus coeruleus and the release of

norepinephrine (NE), which in turn mediates the rapid release of epinephrine by the adrenal medulla and the activation of the sympathetic nervous system. These amygdala CRF neurons show a threshold shift and potentiation in response to repeated and uncontrolled emotional stressors, possibly resulting in generalized anticipatory anxiety (Cook, 2002) (see *Stress-related Potentiation of the Flight-Fight System* in Chapter 6).

The amygdala mediates the hypothalamic stress response by means of a direct pathway via the BNST and an indirect pathway via medullary NE-producing neurons—the primary signal activating CRF production and release. The medial prefrontal cortex forms reciprocal connections with the amygdala, as well as projecting to every major system involved in the mobilization of the stress response. These various prefrontal and subcortical interactions mediate the process of organizing adaptive control expectancies and emotional establishing operations. Increased catecholamine activity associated with acute stressors enhances attention and alertness to environmental stimuli, but with a cost to cognitive functions. Increased dopamine (DA) activity under the influence of stress may reduce prefrontal efficiency, perhaps in vulnerable dogs, significantly disrupting their capacity to perform executive control functions (see *Stress-related Influences on Cortical Functions* in Volume 1, Chapter 3). In human subjects, high cortisol levels in response to moderate stressors are associated with decreased problem-solving capacity, increased arousal and focus on sensory stimuli, and negative mood (e.g., depression, anxiety, and confusion) (Al'Absi et al., 2002).

As a result of an intense threatening event or loss of control (e.g., abusive punishment), NE is rapidly released in the prefrontal cortex and the central amygdala, coordinating a shift from behavior organized in accordance with expectancies and calibrated establishing operations to one of heightened arousal and vigilance, mobilizing the flight-fight system in preparation to escape or attack, if necessary, to secure safety. Under such circumstances, behavioral output may become highly reactive and unpredictable, especially in cases involving a history of abusive treatment. Glucocorticoid negative feedback helps to reverse stress-related arousal by turning off the release of ATCH and by generally quieting the flight-fight system by inhibiting CRF and NE activity while increasing mesocortical DA activity and facilitating serotonin (5-hydroxytryptamine or 5-HT) stress-management functions. Chronic stress, however, appears to gradually exert a global dysregulatory effect on prefrontal and central amygdala functions, while circulating glucocorticoids may slowly degrade the functional fitness of hippocampus (see *Hippocampal and Higher Cortical Influences* in Volume 1, Chapter 3). Chronic stress can be extremely harmful to the integrity of the brain's stress-management system and the dog's ability to adjust adaptively, producing widespread disturbances and dysregulation of DA, 5-HT, and NE systems (see *Startle and Fear Circuits* in Chapter 3). Finally, in addition to playing a central role in the mediation of behavioral stress and anticipatory anxiety, CRF produces a suppressive effect over appetite and facilitates the expression of separation-related distress (Panksepp et al., 1988).

Maternal Separation and Stress

Excessive stress early in a dog's life cycle may disrupt critical neurobiological checks and balances associated with glucocorticoid- and CRF-receptor proliferation and sensitivity, making the puppy more vulnerable to the adverse effects of uncontrollable environmental and social stressors in adulthood. Heim and Nemeroff (1999) have argued that early abuse and emotional trauma in childhood may predispose people to develop a variety of stress-related psychiatric conditions later in life, pointing to CRF sensitization and HPA-system dysregulation as decisive etiological factors. Central CRF activity in the limbic system and brainstem appears to mediate anxiety and other mood disturbances. As the result of early sensitization of the CRF system, even moderate levels of stress may produce significant perturbation of emotional and cognitive functions in adult animals. Early exposure to adverse maternal separation appears to sensitize the HPA system, causing isolation-stressed rats to produce excessive ACTH and adrenal cor-

ticosterone when exposed to psychological stress as adults.

A laboratory model for studying the effects of neonatal handling on adult stress and psychopathology has been developed in rats. Maternal separation can either improve or disturb adult coping abilities, depending on the sort of isolation used. Although brief periods of stressful handling early in life appear to have a highly beneficial effect on an adult animal's ability to cope with stress (Levine et al., 1967), more lengthy exposure to repeated stressful separation from the mother may result in increased sensitivity and vulnerability to stress as an animal matures. The perturbations appear to involve changes in the brain's responsiveness to stressful stimuli, especially central CRF-mediated activation. Plotsky and Meaney (1993), for example, reported that infant rats, when repeatedly separated from their mothers on days 2 to 14 for 180 minutes, exhibit pronounced and persistent changes in the density of CRF-receptor-binding sites and increased CRF-system activity, whereas animals exposed to briefer separation experiences (15 minutes) showed an opposite effect, exhibiting significantly less CRF-system activity than both the 180-minute separation group and the control group that had been left undisturbed during the same period. Ladd and colleagues (1996) found that infant rats deprived of maternal contact for 6 hours on days 2 to 20 exhibited a 59% increase in CRF-receptor-binding sites in the dorsal raphe nucleus, the area involved in the production of 5-HT.

CRF exerts an inhibitory effect on 5-HT production (Kirby et al., 2000)—an effect that may be significantly enhanced as the result of excessive postnatal stress. CRF proliferation in the dorsal raphe nucleus and stress-induced suppression of 5-HT production may play a significant role in the etiology of stress-related dog behavior problems. Reportedly, long-term treatment with paroxetine, a selective serotonin (5-HT) reuptake inhibitor (SSRI), attenuates or reverses the neuroendocrine and HPA-system aberrations produced by stressful maternal separation, normalizing both behavioral and endocrine aspects of the stress syndrome in rats (Ladd et al., 2000). The normalizing effects of SSRIs on the brain's stress-management system may help to explain the therapeutic effects of such medications on stress-related behavior problems. Finally, the effectiveness of SSRIs and tricyclic antidepressants for controlling symptoms of separation distress in dogs suggests a close modulatory role of 5-HT within emotional circuits mediating social behavior and affiliation (Insel and Winslow, 1998).

The loss of familiar attachment objects and places produces significant stress in dogs. Hennessy and colleagues (1997) found that dogs entering a shelter initially exhibit increased levels of cortisol for several days, after which they progressively adapt toward control levels exhibited by dogs living in homes (Figure 4.3). Although separation from an attachment object is often associated with increased glucocorticoid output in adult animals, not all animals show signs of biological stress when they are separated from affiliative partners (Hennessy, 1997). Hennessy suggests that the sudden loss of an attachment object represents a major threat to animals, and the increase in HPA activity may provide the necessary biochemical and metabolic activation to cope with the threats associated with loss and isolation. Perhaps the most important factor determining whether an animal shows signs of stress at separation appears to be the degree of attachment or bonding between the separated animal and the affiliative partner. Dogs separated in an unfamiliar place exhibited increased glucocorticoid activity that was only slightly affected by the presence of a kennelmate (Tuber et al., 1996) (Figure 4.4). Interestingly, though, glucocorticoid levels of separated dogs in the presence of a familiar person, a caretaker who had worked with the dogs for many years, were significantly lower (see *Biological Stress and Separation Distress* in Volume 2, Chapter 4). The differential response of separated dogs to the presence of a familiar dog versus familiar person is difficult to explain. Ostensibly, the separated dog obtains more comfort from the presence of a caretaker than it does from its kennelmate. Precisely why this is so remains unknown, but one possible explanation is that humans represent a supernormal stimulus for social attraction and attachment (see *Supernormal*

Attachment Hypothesis in Volume 2, Chapter 4). Gantt (1944) found that the conditioned anxiety of a dog was markedly reduced by petting but not by the presence of a nearby dog. Perhaps, as the result of selective breeding for traits conducive to companionship with people, dogs may have acquired a genetically influenced preference for contact with people over contact with conspecifics (Feddersen-Petersen, 1994). Odendaal (1999) has reported that interaction between familiar owner-dog dyads results in significantly more oxytocin release than when the dog is exposed to an unfamiliar person, perhaps pointing to a neurobiological basis for the apparent preference of dogs for familiar humans. These physiological differences associated with contact-induced oxytocin activity probably reflect the effects of social conditioning on the mechanisms involved in the release of oxytocin. In any case, puppies exhibit a preference for human contact over canine contact from an early age. Pettijohn and colleagues (1977) found that puppies separated in a strange situation showed a significant reduction in separation distress when in the company of a person. Whether involving active or passive contact, the proximity of a human was more comforting to the puppy than the presence of its own mother. Surprisingly, the presence of the mother was no more effective at assuaging separation distress in a strange situation than was the presence of an unfamiliar adult dog (see *Social Attachment and Separation* in Volume 1, Chapter 2). As a social stimulus, the human being may be a better activator of oxytocin activity in dogs that show a preference for humans over other dogs—a hypothesis that would be easy to test. According to Panksepp (1992), in the context of maternal care, oxytocin may centrally stimulate emotions conducive to social approach and contact:

> A straightforward emotional prediction is that brain oxytocin may evoke warm positive feelings of social strength and comfort when aroused by peripheral stimuli. For instance, as mother and infant share in the nursing experience, brain oxytocin systems may be activated in both individuals through reciprocal somatosensory and gustatory stimulation. This would contribute to a sense of ease and relax-

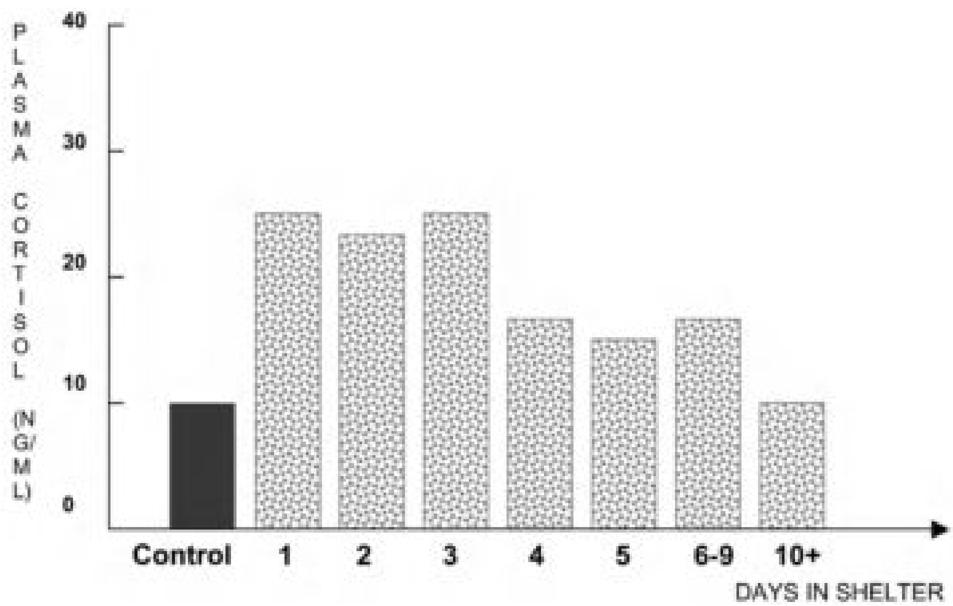

FIG. 4.3. Upon entering a shelter, dogs show a significant increase of HPA (hypothalamic-pituitary-adrenal)-axis activity. The first 3 days appear to be particularly stressful. After day 10, however, most dogs appear to be physiologically adapted to the new situation. After Hennessy et al. (1997).

> ation (feelings of acceptance and nurturance) and thereby tend to promote conditional attraction (i.e., social bonding/imprinting) between caregivers and receivers. These are the types of neuroaffective changes that would also tend to counteract feelings of isolation and distress. (243–244)

In conjunction with endogenous opioids, oxytocin performs various neuroregulatory roles in the process of modulating stress responses and coordinating dynamic neurobiological changes conducive to social bonding and the development of complex social behavior (see *Oxytocin-opioidergic Hypothesis* in Chapter 6). Like endogenous opioids, oxytocin also exerts a significant inhibitory effect over separation-distress vocalizations.

PHARMACOLOGICAL CONTROL OF SEPARATION DISTRESS

Since the cascade of events leading to full-blown separation-related panic includes the activation of the brain CRF system, drugs capable of blocking CRF-receptor sites or restraining CRF activity would probably prove beneficial in the management of separation-related problems. In addition to SSRIs, such as paroxetine, tricyclic antidepressants appear to provide such regulatory enhancement. Imipramine, for example, appears to exert a pronounced effect on CRF activity (Sternberg and Gold, 1997):

> In rats, regular, but not acute, administration of the tricyclic antidepressant imipramine significantly lowers the levels of CRH [corticotropin-releasing hormone] precursors in the hypothalamus. Imipramine given for two months to healthy persons with normal cortisol levels causes gradual and sustained decrease in CRH secretion and other HPA-axis functions, indicating that down-regulation of important components of the stress response is an intrinsic effect of imipramine. (13)

Given the complementary roles of CRF as a trigger for separation reactions and the efficacy of oxytocin to quiet them, Panksepp (1998) has suggested that medications capable of restraining central CRF activity while enhancing oxytocin activity might prove

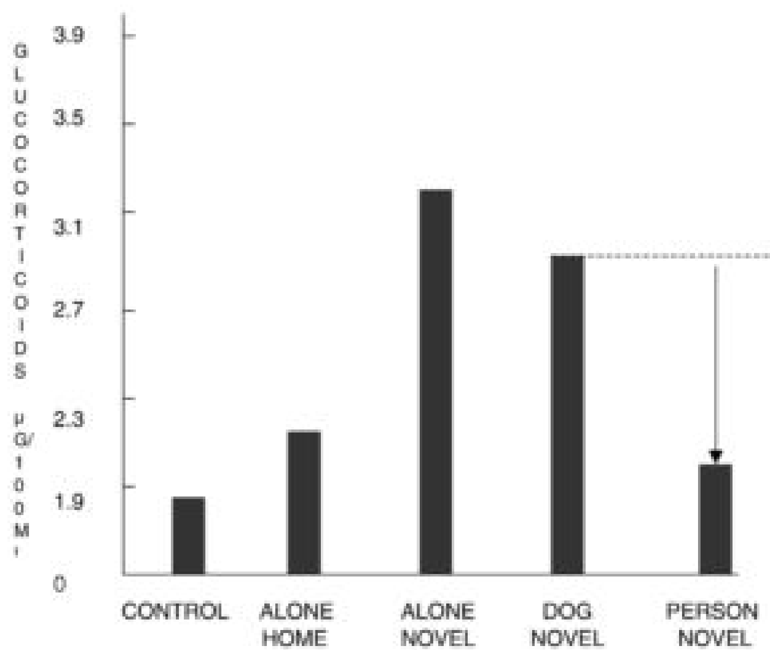

FIG. 4.4. Stress response to social contact and separation in novel and home environments. Note the increased effect of a person on a dog in a novel environment versus the effect of a familiar dog. Maximum distress occurs when the dog is left alone in an unfamiliar environment. Adapted from Tuber et al. (1996).

efficacious in the treatment of separation-related problems. Recently, promising strides have been made in the development of CRF receptor (subtype 1) antagonists (Gilligan et al., 2000; He et al., 2000). These compounds appear to have excellent oral availability, potent anxiolytic efficacy, and minimal side effects. Similarly promising advances have been made in the development of an orally available substance P antagonist (MK-869), a compound that appears to be highly effective in the management of depression and may eventually prove beneficial in the management of separation-related problems (Kramer et al., 1998). Medications with the capacity to block CRF and substance P activity offer exciting possibilities for the treatment of stress-related dog behavior problems and deserve preclinical and clinical veterinary investigation.

The preponderance of evidence supports the view that different emotional circuits mediate the expression of separation distress (panic system) and anxiety (fear system) involving the cingulate gyrus, the preoptic and ventral septal areas, the dorsomedial thalamus, the BNST, and the PAG (Panksepp et al., 1985; Panksepp, 1998). Although panic and fear systems appear to exert a reciprocal excitatory influence on one another, they are motivationally distinct systems (see *Emotional Command Systems and Drive Theory* in Chapter 6). However, certain fears, such as thunderstorm phobias, are highly correlated with separation distress (Overall et al., 2001), suggesting the possibility that the sensitization of the fear system (e.g., the occurrence of a severe thunderstorm) occurring at times when the owner—the dog's source of safety—is absent may play a role in the etiology of SDS. Many separation-reactive dogs do not show evidence of noise or thunderstorm phobias, consistent with the notion that SDS is complex in origin and affected by several causes and contributing influences. Despite the reciprocal excitatory influences exerted by fear on panic and by panic on fear, separation distress and the panic circuits mediating its expression operate with significant independence from anxiety and fear—an observation supported by both psychobiological (Panksepp, 1998) and pharmacological studies. For example, Scott and colleagues (1973) found that separation-distress vocalization in beagle puppies was not ameliorated by anxiolytic medications (e.g., chlorpromazine, reserpine, meprobamate, and diazepam), but was rapidly and consistently reduced by imipramine:

> In sufficient doses, it [imipramine] will reduce vocalization to essentially zero without producing abnormal behavior or adverse physiological side effects. Even under the largest doses, the dogs that received imipramine appeared to be no different from the controls that were given placebos, except for their vocalization rates. (17)

Imipramine produced both immediate and sustained relief from separation distress. Even though diazepam had no discernible effect on separation-distress vocalizations, treated puppies appeared to be more relaxed when handled. In the case of infant rhesus monkeys, however, diazepam has been demonstrated to produce a potent attenuating effect on separation-related stress (Kalin et al., 1987), suggesting the possibility that different aspects of the separation stress response are under the control of different regulatory neurotransmitter systems in dogs and monkeys.

Although imipramine was highly effective in controlling the separation-induced vocalizations produced by beagles and Australian terrier-beagle crosses, the drug did not control the separation-distress vocalizations exhibited by shelties and Telomians. These findings suggest that the effects of tricyclic antidepressants on SDS may be highly variable depending on the breed and temperament of dog. Observing that such drugs exert variable behavioral effects on dogs depending on breed type should not be surprising, however. Arons and Shoemaker (1992), for example, found that dogs of different breeds (e.g., Border collies, shar planinetz, and Siberian huskies) exhibit significant neurobiological variability with respect to neurotransmitter levels localized in different brain areas, as well as exhibiting differences in the expression of highly influential receptor sites (Niimi et al., 1999). These fundamental differences exert profound influences on behavioral thresholds and the dog's response to medication. Evidence of breed-related variability at the level of neural organi-

zation underscores the importance of medicating dogs according to breed-specific differences, recognizing that they are not all cut from the same neurobiological cloth.

Panksepp and colleagues (1978) found that pronounced alleviation of separation distress could be achieved in puppies with the administration of very low doses of morphine. Medicated puppies behaved normally, without signs of sedation, except that they appeared comfortable and calm while separated from mother and littermates. The benefit of morphine, however, is dose dependent, with larger doses resulting in catalepsy or, paradoxically, more separation-distress vocalization. Morphine has also been shown to control separation-distress vocalization effectively in infant rhesus monkeys, without reducing activity levels (Kalin et al., 1987). The efficacy of morphine and other opiates is dramatic, but the clinical feasibility of such medications for the treatment of SDS is limited because of the potential for abuse, rapid tolerance, and eventual withdrawal symptoms that might worsen the symptoms of SDS when the treatment is discontinued. Nonetheless, morphine in low doses (perhaps in combination with imipramine) may have a therapeutic application in the management of acute separation-related panic, especially in cases where other medications have failed.

Voith and Borchelt (1996) have suggested that a wide variety of drugs (including benzodiazepines, neuroleptics, progestins, and tricyclic antidepressants) may have some usefulness in the treatment of separation distress. Historically, the tricyclic antidepressant amitriptyline has been the most commonly prescribed medication for the control of problematic separation-related behavior. A possible added benefit of amitriptyline is a sedative effect, probably stemming from a potent blocking effect on histamines. Amitriptyline exerts a ninefold greater blocking effect on histamines than does imipramine (Julian, 1995). Benzodiazepines (e.g., clorazepate or alprazolam) are often used in combination with tricyclic antidepressants or SSRIs to enhance effectiveness, especially in cases where SDS presents comorbidly with a phobia associated with being left alone or a high level of anticipatory anxiety associated with departures. Neuroleptic medications, such as acepromazine, are occasionally used to suppress temporarily the motor expressions of acute separation distress, but they have very limited value with respect to targeting the underlying emotional arousal pathways triggering with separation distress and are generally reserved for emergencies.

More recently, the tricyclic antidepressant clomipramine, a potent 5-HT-reuptake inhibitor, has become increasingly popular for the treatment of separation-distress problems. Although clomipramine has shown promise for the management of separation-related behavior (Simpson, 1997), Podberscek and colleagues (1999) have questioned its value in the treatment of separation anxiety. In their study, the efficacy of clomipramine was evaluated as an adjunct to behavior therapy. Although clomipramine appeared to produce a significant sedative effect, it was not "any more effective than a placebo as an adjunct to behavioural therapy in the treatment of separation-related behaviour problems in dogs" (369). Hewson (2000) has criticized their study and Simpson's previous report, concluding that neither behavior therapy nor clomipramine alone or both together have been shown to control separation-related behavior problems effectively. A subsequent study, however, reported by King and colleagues (2000) indicates that clomipramine in combination with behavior therapy does significantly reduce separation-related destructiveness and elimination problems, though the combination does not significantly attenuate separation-related vocalization excesses. They suggest that the previous failure of Podberscek and colleagues to detect a reliable effect of clomipramine was due to shortcomings in the study's design (e.g., sample size).

Panksepp (personal communication, 1996) has suggested that clonidine in combination with morphine, imipramine, or a 5-HT-reuptake inhibitor (e.g., clomipramine) *might* be beneficial in the treatment of separation-related distress in dogs. Clonidine is an NE-receptor agonist that exerts mixed excitatory (postsynaptic) and inhibitory (presynaptic) effects on NE activity (Panksepp, 1998). Evidence for a beneficial role of clonidine in combination with imipramine for the control

of separation distress has been reported in squirrel monkeys (Harris and Newman, 1987); in rhesus monkeys, however, clonidine alone reduced activity levels, but without influencing separation-distress vocalizations (Kalin et al., 1988). Interestingly, clonidine in combination with passionflower (*Passiflora incarnata*) has been shown to exert a significantly superior effect over clonidine alone in the management of mental symptoms associated with opiate withdrawal (Akhondzadeh et al., 2001). An SSRI that may offer significant efficacy in the control of SDS with panic is paroxetine, which appears to influence the CRF system beneficially as well as enhance serotonergic activity, with proven efficacy in the control of human panic disorder, general anxiety disorder, and obsessive-compulsive disorder (Ballenger, 1999).

Lastly, some owners have reported success using over-the-counter drugs such as melatonin, which has been shown to modulate separation distress in chicks (Nelson et al., 1994), separation anxiety exhibited by a bear that failed to hibernate (Uchida et al., 1998), and fear of noises (Aronson, 1999). Dodman (1999) has used melatonin with some apparent success in the treatment of compulsive licking and thunderstorm phobias. Melatonin appears to modulate endogenous opioid activity, perhaps providing an opioid-mediated regulatory influence on attachment processes and separation-related distress. A bidirectional feedback relationship appears to exist between melatonin and endogenous opioids, with melatonin inhibiting opioid activity and opioids stimulating melatonin activity (Barrett et al., 2000). These findings suggest that the putative effects of melatonin on separation distress may not be mediated directly by an increase in opioid activity, but via an indirect influence existing at another level of interaction between melatonin and opioids. In rats, melatonin has been shown to attenuate the adrenocortical response to stress, to increase HPA-axis responsiveness to glucocorticoid feedback effects, and may ameliorate stress-related disturbances associated with chronic stress (Konakchieva et al., 1997). Melatonin also appears to perform a protective neuroregulatory role over the immunosuppressive effects of stress by various means (Pierpaoli and Maestroni, 1987). Finally, Pacchierotti and colleagues (2001) have conjectured that stressed animals may produce increased amounts of melatonin in an effort to stabilize internal states associated with anxiety and agitation.

Some experimental evidence indicates that melatonin may exert an inhibitory effect over thyroid activity in various animal species (Wright et al., 2000). To my knowledge, the thyroid-inhibiting effects of melatonin have not been explicitly demonstrated in dogs, but the existence of such a potential side effect warrants careful use of melatonin in the case of dogs showing borderline thyroid levels or behavioral conditions believed to be under the influence of thyroid insufficiency. Aronson (1998) has suggested that thyroid insufficiency may play a significant role in the etiology of a wide variety of behavior problems and has been associated with aggression in dogs (Fatjó et al., 2002) (see *Assessment and Identification* in Volume 2, Chapter 8). In addition, recent research shows that thyroid hormones produce an augmentative effect over cognitive functions via the enhancement of cholinergic activity, emphasizing the far-reaching influence of the hormone (Smith et al., 2002). The short-term and long-term side effects of melatonin therapy in dogs are unknown. In people, melatonin appears to be well tolerated, and the risk of toxicity is low at prescribed dosages (De Lourdes et al., 2000).

Note: The foregoing information is provided for educational purposes only. If considering the use of medications to control or manage a behavior problem, the reader should consult with a veterinarian familiar with the use of drugs for such purposes in order to obtain diagnostic criteria, specific dosages, and medical advice concerning potential adverse side effects and interactions with other drugs.

POTENTIAL ALTERNATIVE TREATMENTS

Herbal Preparations

Numerous studies (especially in Germany) have investigated the efficacy of St. John's wort, *Hypericum perforatum*, for the manage-

ment of mild to moderate depression in people (Josey and Tackett, 1999). Hypericum (0.3% hypericin) has been shown to perform on a par with imipramine, amitriptyline, and fluoxetine for the treatment of depression (Bergmann et al., 1993; Vorbach et al., 1994; Harrer et al., 1999), strongly suggesting that it may have some therapeutic value for the management of SDS and other behavior problems treated successfully with SSRIs and tricyclic antidepressant medications (e.g., compulsive excesses). Pharmacological studies in rodents indicate that hypericum extracts influence dopaminergic, serotonergic, and noradrenergic reuptake mechanisms (Mueller and Rossol, 1994; Muller and Schafer, 1996; Kaehler et al., 1999). St. John's wort has been shown to increase DA and 5-HT metabolite levels, but without affecting monoamine oxidase activity, suggesting the possibility that the herb exerts its pharmacological effects by inhibiting DA or 5-HT reuptake (Serdarevic et al., 2001). Steger (1985) found that a combination of hypericum and valerium proved more effective for the control of depressive symptoms than did desipramine, a tricyclic antidepressant having pronounced noradrenergic reuptake effects. The combination of the two herbal preparations appears to produce a synergistic effect. So far, the side effects of hypericum have been repeatedly described as minimal when the herb is taken at recommended dosages, but no studies to my knowledge have been performed demonstrating efficacy or safety with dogs. The ingestion of large amounts of St. John's wort may cause gastric disturbances or phototoxicity. Although several studies have indicated that St. John's wort is an effective treatment for mild depression, Davidson and colleagues (2002) failed to detect a therapeutic benefit resulting from hypericum treatment for moderately severe-major depression in human patients. Among the patients studied, hypericum was no more effective than its matched placebo. Interestingly, however, sertraline, a potent SSRI commonly used to treat depression, failed to perform much better than hypericum in terms of primary outcome measures, leaving some questions open for future study. Finally, Fornal and colleagues (2001) have directly measured the discharge rate of 5-HT neurons in the dorsal raphe nucleus after administering St. John's wort to awake cats. They found that St. John's wort had no effect on neuronal activity, in sharp contrast to the robust effects produced by fluoxetine and sertraline. Both SSRIs produced a marked reduction of neuronal activity by increasing synaptic 5-HT levels. These findings suggest that the putative effect of St. John's wort may be mediated by a mechanism other than 5-HT-reuptake inhibition.

Two other herbal preparations that may exert some modulatory control over the distress associated with separation are ginkgo biloba and kava kava. Porsolt and colleagues (1990) reported that preventive dosing with ginkgo biloba prior to repeated inescapable shocks produced a significant protective influence against stress associated with learned helplessness. The blocking effects of ginkgo biloba against symptoms of learned helplessness were more robust than the effects produced by diazepam and did not impair passive avoidance learning—a side effect observed to occur in association with benzodiazepines. Finally, some evidence suggests that kava extract may modulate circuits controlling separation distress. Many double-blind, randomized, and placebo-controlled trials have demonstrated the efficacy of Kava extracts (30% kavalactones) for the symptomatic treatment of anxiety (Pittler and Ernst, 2000). Kava extracts have also been shown to attenuate separation-distress vocalizations and stress-induced analgesia in 8-day-old chicks (Smith et al., 2001). Whether similar effects might occur in dogs is not known. Scattered reports associating the use of kava kava with severe side effects, including liver damage, have recently called the safety of herb into question. Although serious side effects do appear to occur sporadically, they appear to be relatively rare when kava kava is taken without other drugs for short periods at recommended dosages (Stevinson et al., 2002). The potential benefits and side effects of kava kava for the management of separation-related problems in dogs is unknown; nonetheless, it is widely used, alone or in combination with St. John's wort, by dog owners seeking an over-the-counter cure for separation-related stress, often without veterinary guidance and support.

Herbal preparations that are capable of producing a clinical benefit should be considered prima facie capable of producing harmful side effects if improperly used. In addition, herbal remedies may interact synergistically with other medications in ways that could be potentially harmful to a dog, requiring that such remedies be carefully evaluated for safety before considering their use (Cooper, 2002). Consequently, like other medications used in the control and management of behavior problems, complementary herbal and dietary regimens should be introduced under the close supervision of a veterinarian familiar with the various clinical effects and side effects of such treatment programs.

Dog-appeasing Pheromone

A synthetic analogue of apaisine, a pheromone reportedly produced by lactating female dogs, may exert a beneficial modulatory effect over separation distress. The putative pheromone is believed to produce a calming effect on nursing puppies. Unfortunately, the basic scientific evidence supporting these potentially exciting and breakthrough findings remains to be published. To the best of my knowledge, the procedures used to isolate and synthesize the pheromone, its biochemical characteristics and molecular description, and evidence in support of its putative emotional and behavioral effects on puppies and adult dogs have not yet been published in a peer-reviewed scientific journal. Pheromones are captured by the vomeronasal organ and processed by the accessory olfactory bulb. Although dogs lack a true flehmen response, they do exhibit tonguing—a flehmenlike response that appears to collect pheromone molecules from the air and surfaces where they have been deposited (see *Vomeronasal Organ* in Volume 1, Chapter 4). Preliminary results of a multicenter study are promising, showing that the synthetic analogue, marketed as dog-appeasing pheromone (DAP), may produce a clinical effect comparable to clomipramine when used in combination with behavior therapy to treat separation-related behavior problems (Gaultier and Pageat, 2002). Curiously, though, given the robust release of oxytocin and prolactin during nursing (Uvnäs-Moberg et al., 1985), it seems odd that a functionally redundant pheromone would also be genetically coded to produce an appeasing effect in support of an activity that is intrinsically calming for a puppy to perform in the first place. A plug-in electric diffuser supplied with the product dispenses DAP into the air. In addition to possibly helping to calm separation-reactive dogs, DAP is believed to reduce stress and fear. Another proposed use of DAP is to facilitate a puppy's transition into the home or ease the acceptance of stressful environmental changes (e.g., moving). Perhaps the appeasing pheromone can be harvested by wiping the intermammary line of lactating females with gauze moistened with dilute alcohol. The collected material can then be mixed with water and dispensed from a spray bottle or other means (e.g., placed on toys). Also, sending home towels and bedding containing the odors of the mother may help to facilitate the puppy's transition into the new home. In any case, pheromone or not, maternal odors may produce beneficial emotional effects by means of conditioned associations.

Note: The foregoing information is provided for educational purposes only. If considering the use of herbal remedies, the reader should consult with a veterinarian familiar with the use of such preparations to obtain specific dosages, diagnostic criterion for their use, and medical advice regarding potential side effects.

SEPARATION DISTRESS AND DIET

In the past, dog owners were frequently advised to make various dietary changes for the purpose of altering a dog's behavior or motivation. Most of these recommendations have come and gone, leaving in the wake a high degree of skepticism about the usefulness of dietary manipulations for the management of behavior problems. Undoubtedly, the quality, quantity, and combination of foods eaten by a dog exert some influence, but the extent of these influences and the specifics involved remain to be disclosed by animal psychodietetic research (Ballarini,

1989). What little is known, however, may be useful for managing some problems associated with separation distress, anxiety, and panic. For example, the physiological arousal and aversive motivational tensions associated with hunger may increase exploratory and destructive activities when a dog is left alone. A full stomach may help dogs to relax and sleep when alone. Consequently, it may be useful to feed separation-reactive dogs in the morning rather than in the evening. In addition to morning feedings, Mugford (1987) suggests that a high-fiber diet may help to calm separation-reactive dogs and reduce destructiveness, but provides little evidence to support this claim. Growing evidence suggests that essential fatty acids (EFAs), especially omega-3 fatty acids (fish oils), may alter negative mood and alleviate depression (see *Aggression and Diet* in Chapter 7). In addition, some evidence suggests that olive oil may also exert some benefit on mood (Puri and Richardson, 2000). Olive oil is a rich source of oleic acid, the nutritional precursor of oleamide, a psychoactive lipid. Oleamide appears to play a significant role in sleep induction and the modulation of serotonergic neurotransmission (Huidobro-Toro and Harris, 1996; Thomas et al., 1998). The anxiolytic effects of diets rich in soy may be beneficial in some cases of SDS presenting comorbidly with anxiety and fear (Lephart et al., 2002). Although dietary change and supplementation may provide a nutritional benefit for the management of separation-related problems, the efficacy of such nutritional supplementation for the management of SDS remains to be clinically evaluated and should be considered on a case-by-case basis under the advisement of a veterinarian.

Various preservatives, additives, flavorings, and dyes used in the manufacture of dog food have been suspected of producing a wide variety of effects on behavior, but no solid evidence is yet available to support the widely held conviction (Halliwell, 1992). A common source of allergies among dogs is food, suggesting that certain foods might produce neurotropic allergies that could contribute to the development of behavior problems, including SDS. Excessive sugar in the diet has been frequently pointed to as a cause of hyperactivity in children, but no solid scientific evidence supports the hypothesis (see *Dietary Factors and Hyperactivity* in Volume 2, Chapter 5).

One isolated report has suggested that diet plays a dramatically significant role in the treatment of behavior problems (Anderson and Marinier, 1997). The authors claim that a significant benefit may be obtained by feeding dogs according to their preferences, that is, giving them a choice in the foods they eat. By merely adjusting the diet to reflect the dog's preferences (e.g., feeding fresh meat, well-cooked vegetables, and raw knuckle bones) and avoiding excessive exercise or excitement, they claim that behavioral complaints were drastically reduced in 98% of the 100 dogs observed in their study. Unfortunately, as a result of limited information concerning the procedures used to assess behavioral change and collect data, the absence of experimental controls, a lack of rigorous statistical analysis, and other experimental design problems, it is impossible to assess the value of these findings. For what it is worth, however, Beaver and colleagues (1992) found that most dogs prefer meat over vegetables, especially cooked fresh meat, which they prefer over raw meat. When given a choice, their top choices were fried liver with onions (see the following note) and baked chicken, followed by cooked beef and fish. Aged meats (cooked and raw) were significantly less attractive than fresh cooked meats. The least attractive food items were fruits. (*Note:* Onions are toxic to dogs and can cause hemolytic anemia, a blood disease in which red blood cells are damaged and destroyed. Dogs should not be fed onions.)

Dietary supplements that may have some merit for the management of SDS are milk products containing casein. Casein is found in milk powder and cottage cheese. The digestion of casein produces casomorphins, naturally occurring opioids that are absorbed into the bloodstream (Panksepp et al., 1985). Other exorphins (or exogenous opioids) are produced as the result of the duodenal digestion of cereal glutins (Ballarini, 1990). Since separation-distressed animals appear to be highly responsive to morphine, it would seem

sensible to investigate the effect of casomorphins and other exorphins on separation distress. Perhaps the habit of sending children off to school after a meal of cereal and milk is no accident, but an unwitting nutritional remedy for the reduction of childhood separation anxiety. The notion that casein from the mother's milk might mediate social attachment by way of an opioid mechanism offers some intriguing, but as yet untested, possibilities with regard to the influence of nutrition on attachment and separation-related behavior. Whatever the specifics, attachment and separation are orchestrated by an intricate web of psychological and physiological interactions involving complex neural systems regulating emotions associated with comfort and distress.

Finally, considering the significant role of 5-HT in the regulation of impulsive behavior, the modulation of fear and anxiety, and the neural management of stress, it would seem advisable to provide separation-reactive dogs with a diet that maximizes the utilization of nutritionally derived tryptophan (see *Diet and Serotonin Activity* in Volume 1, Chapter 3). Diets combining low-protein and high-carbohydrate content appear to increase the availability of peripheral tryptophan, the amino acid precursor of 5-HT. In addition, increased exercise may stimulate increased 5-HT production and help optimize tryptophan transport across the blood-brain barrier (Meeusen and De Meirleir, 1995)(see *Exercise and Diet* in Chapter 3). In addition to providing an acceptable outlet for agitated oral activity, chewing may evoke an insulin release enhancing tryptophan access to blood-brain barrier transport molecules (see *Nutrition and Aggression* in Volume 2, Chapter 6).

Early Stimulation, Separation Exposure, and Emotional Reactivity

The successful control and management of SDS depend first and foremost on accurate diagnosis and complementary behavior therapy (Marder, 1991). Although drugs may help in some cases, the long-term benefits of drug therapy depend on the implementation of behavioral techniques designed to help improve the quality of the human-dog relationship and to enhance the dog's ability to cope with separation. Medicating dogs exhibiting separation panic and anxiety problems on a long-term basis in the absence of behavior therapy and training is a highly questionable practice and should be avoided.

As the result of prenatal and postnatal stress, social or environmental deprivation, disorderly or abusive social interaction, excessive restraint, traumatic loss of trust, or a failure to form a trust-based bond, dogs may be predisposed to show reactive rather than adaptive coping styles in response to stressful circumstances. Dogs that have lost their ability to form reliable control expectancies may fixate on reactive adjustments, that is, develop behavior problems in association with a persistent condition of behavioral stress and tension stemming from an inability to experience relief or obtain reward. From the cynopraxic perspective, the working assumption in such cases is fivefold:

1. The dog has become incompetent as the result of a failure to establish an adaptive behavioral framework of prediction-control expectancies with which to obtain its basic needs for comfort, safety, and reward.
2. The dog needs a highly predictable and controllable base of interaction with a friendly human leader to attain the behavior- and mood-modifying benefits of reward produced by positive prediction error and adaptive modal activity.
3. Effective prediction and control lead to competence, confidence, and the counterconditioning benefits of relaxation inherent to an adaptive coping style.
4. By means of affectionate and fair exchanges involving petting, food, and play performed in the context of cooperative and mutually rewarding interaction, a potent normalizing effect is produced.
5. The outcome of such interaction is a friendly and stable bond and an enhanced life experience for both the owner and the dog.

Behavioral distress is expressed in the form of anxiety and frustration, whereas tensions take

the form of increased irritability, intolerance, and emotional reactivity. Anxiety and frustration are closely associated with the development and expression of dysfunctional prediction-control expectancies. Anxiety is a state in which a dog is unsure of its ability to predict a pending event, whereas frustration is the result of a failure to control the event once it occurs. Together, anxiety and frustration form a problematic axis of failure with respect to the attainment of emotional relief and reward. Competency is restored through attention and basic training, integrated compliance training, posture-facilitated relaxation (PFR) training, and other reward-based techniques and procedures, providing the dog with the means to learn and to expect relief and reward by behaving in accord with predictive signals. Training and behavior-modification strategies emphasizing intrusive and aversive loss of control in such cases may only worsen the dog's chances of recovery.

The precise causal mechanisms underlying SDS are not known, but many likely etiological factors and coactive influences have been identified (see *Separation Distress and Coactive Influences* in Volume 1, Chapter 4). Although the formation of excessive attachment and dependency appears to play contributory roles, many dogs are exposed to such influences without becoming overly reactive when left alone. Dogs unaccustomed to being left alone may not have acquired the emotional coping skills needed to accommodate the stress produced by abrupt separation. Dogs exhibiting unstable-introverted temperaments (melancholic) may be more prone to develop separation-related problems associated with anxiety (despair), whereas dogs exhibiting unstable-extraverted temperaments may tend to develop separation-related problems associated with frustration (protest). Whether SDS is associated with symptoms of anxiety or frustration, the panic emotional command system appears to mediate the expression of separation distress (Panksepp, 1998).

Numerous theories have been postulated to help explain developmental disturbances resulting in excessive distress or panic at separation (see *Attachment and Separation* in Volume 1, Chapter 4). A convincing account remains to be fleshed out, but genetics (see Lakatos et al., 2000; and Hofer et al., 2001), early stimulation, and traumatic experiences with separation probably all play a significant role in the etiology of SDS. Neonatal traumatic handling and excessive environmental stress resulting from excessive temperature changes, nutritional deprivation, physical trauma, maternal neglect or isolation, inadequate housing, or abuse may exert a lasting adverse effect on neurobiological substrates mediating stress and stress-related coping behaviors. An absence or an excess of postnatal stress may produce long-term adverse effects on a dog's health, emotional reactivity, and its ability to cope with stressful situations, that is, situations requiring adaptive adjustments.

Prenatal Stimulation

Prenatal stress appears to affect adversely a progeny's ability to cope with environmental and psychological stress. Thompson (1957) found that exposing gestating female rats to intense fear-eliciting stimulation resulted in unstable and emotionally overreactive offspring. Human infants of depressed mothers exhibit a variety of endocrine and behavioral changes associated with increased sympathetic arousal (e.g., high cortisol and NE levels coupled with low DA and 5-HT levels). Such babies appear to exhibit depressive tendencies, including decreased orienting responsiveness, flat affect, reduced activity levels, and increased irritability. Providing the rat mother with stimulation appears to produce a beneficial effect in her offspring. Adler and Conklin (1963) found that exposing gestating rat mothers to repeated daily handling helped to reduce emotional reactivity in their offspring as adults. Prenatal stress, in the form of unpredictable noise and light stimulation occurring three times weekly, during the gestation period increases basal levels of corticosterone as well as sensitizes the sympathetic-adrenomedullary (SAM) system to stress, as evidenced by increased secretion of NE and epinephrine in response to foot shock (Weinstock et al., 1998). Animals exposed to excessive prenatal stress exhibit attentional deficits, increased anxiety, and disturbed social behavior. Prenatal stress dysregulates the HPA system. In response to aversive stimulation,

prenatally stressed animals exhibit a prolonged elevation of peripheral glucocorticoid levels, together with decreased negative-feedback inhibition of CRF release by the hypothalamus. In addition, animals stressed during gestation show higher levels of CRF in the amygdala, have fewer glucocorticoid receptor sites in the hippocampus, produce fewer opioid peptides, and exhibit decreased GABA-benzodiazepine inhibitory activity (Weinstock, 1997). In combination, the effects of prenatal stress are pronounced and potentially very influential on the emotional and behavioral development of dogs. Gestating females should be shielded from excessively stressful conditions and receive regular play and other enrichment activities. Postparturient mothers showing signs of stress, anxiety, or depression may benefit from brief biweekly massage (Field et al., 1996a,b).

Postnatal Stimulation

Postnatal stimulation appears to exert pronounced effects on an animal's ability to cope with emotionally provocative situations and stress as an adult. Considerable research has demonstrated that postnatal handling of rats during the first 3 weeks of life permanently alters the way in which they cope with environmental and psychological stressors. Briefly handled rats show decreased levels of CRF, ACTH, and plasma corticosterone levels, appearing to significantly benefit from such exposure to stress. In addition, such animals show an improved ability to recover homeostatic balance (return to basal corticosterone levels) after the stressor is removed (Plotsky and Meaney, 1993). According to Denenberg (1964), an inverse relationship exists between the amount of stimulation that a neonate receives and its emotionality as an adult. High levels of neonatal stimulation are correlated with reduced adult emotionality, whereas low levels are correlated with increased adult emotionality (Figure 4.5). Dennenberg's curve holds true only with respect to stimulation occurring within an optimal range of exposure, with excessive amounts of early stress producing adverse effects on a dog's development. Puppies that receive inappropriate, insufficient, or excessive contact stimulation and separation exposure may be more prone to exhibit problematic emotionality at separation as adults. The aforementioned studies involving stressful maternal separation show that excessive neonatal exposure to stressful isolation results in lasting disturbances in CRF and HPA activity. Maternally stressed animals exhibit an increased sensitivity to stress and show heightened emotional reactivity and anxiety when exposed to aversive situations, effects also exhibited by animals shielded from environmental stress in infancy. The effects of maternal stress appear to be dose dependent, with little or no stimulation in infancy producing similar sorts of effects as seen in the case of animals exposed to excessive stress (Plotsky and Meaney, 1993). In addition to modulating stress and emotional reactivity beneficially, early handling may improve a dog's ability to cope with adversity and thereby enhance its trainability and problem-solving abilities (see *Early Development and Reflexive Behavior* in Volume 1, Chapter 2). Unfortunately, scant data is available to

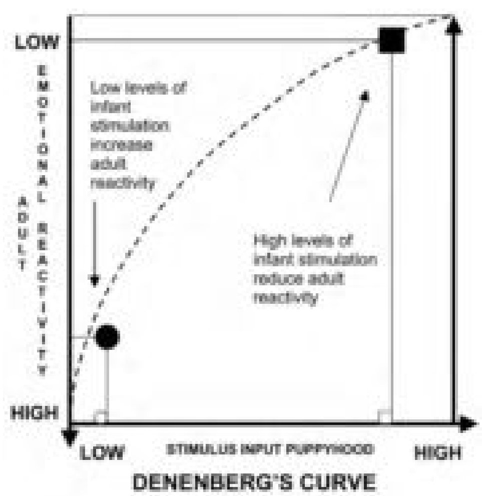

FIG. 4.5. Early infant stimulation exerts a pronounced effect on adult reactivity levels. Whereas moderate levels of tactile stimulation and environmental stress produce a beneficial effect on reactivity levels, too little or too much stimulation may produce adverse effects by increasing adult emotional reactivity levels (choleric type) or decreasing adult emotional reactivity (melancholic type), respectively. Adapted from Denenberg (1964).

confirm the benefits of early handling in dogs, but extensive research with rodents and anecdotal reports of benefits in working dogs (e.g., the Biosensor Research Team) suggest that handling may be a valuable husbandry tool in the case of military working dogs (Fox, 1978).

Handling and Gentling

Various handling procedures have been suggested for maximizing the benefits of early stimulation. The techniques vary but typically involve repeated brief periods of maternal separation from birth to 3 to 5 weeks of age, although postnatal week 1 may be the optimal period for handling effects to occur (Fox, 1971). The necessary amount of handling stress probably varies significantly from breed to breed and individual to individual, depending on genetic predisposition to stress. In addition to maternal separation, thermal stress (placing a puppy on a cold surface) and vestibular stimulation (produced by rocking a puppy side to side on a tilting board) for 1-minute periods each have been suggested by Fox (1978). Fox also recommends that thermal stress and vestibular stimulation be followed by an equal time devoted to gentle stroking. The Monks of New Skete (1991) place individual neonates into cardboard boxes and leave them there for 3 minutes, followed by a period of gentle stroking before the puppy is returned to its mother and littermates.

Perhaps, simply picking a puppy up daily and weighing it on a cold wobbly scale may provide sufficient biological stress to integrate a balanced flight-fight system. Further, given the potential long-term risks associated with maternal separation distress, perhaps adversely sensitizing stress-mediating circuits and inadvertently increasing the puppy's risk of showing stress-related problems in adulthood, the possible health and behavioral benefits of exposing puppies to such stress may not outweigh the potential harm. Consequently, without additional and unambiguous evidence concerning the benefits of such treatment for puppies, exposing neonates to maternal separation and isolation distress might best be avoided until appropriate studies are performed to show, first of all, that isolation distress is beneficial, and then to precisely define the dosage needed, that is, how much isolation exposure is beneficial and at what point does it become harmful. Puppies without a mother should receive intensive neurological stimulation produced by evoking the full range of neonatal and transitional reflexes described by Fox (1965) (see Figure 2.4 in Volume 1).

Gentling refers to procedures in which a puppy is stroked while being held in various nonthreatening positions. In addition, the handler may gently blow breath around the puppy's head and face. Field and colleagues (1996b) have found that massaging infants delivered to depressed mothers exerts significant benefits on attention, emotionality, and sociability test scores. Such infants are often born with stress-related changes, including increased cortisol and catecholamine levels, both of which are significantly reduced by two 15-minute periods of massage per week. The puppy can also be exposed to brief periods of massage while restrained in various positions (stand, sit, down, and lateral roll). Brief restraint represents a mild source of stress, and massage may help a puppy learn to modulate and refine its response to it. Gentling is believed to enhance bonding and taming. Among rats, postweaning gentling has been shown to exert significant benefits, including enhanced learning and retention, increased exploratory behavior, improved competitive success (social dominance), and improved stress response (Morton, 1968). Gentling may be particularly beneficial in the case of puppies exhibiting signs of excessive fear or contact aversion.

Exposure to maternal separation distress, cold, and distressful noxious manipulations appears to integrate a potent flight-fight stress system via AVP and CRF. In contrast, the repeated nonnoxious evocation of oxytocin release appears to integrate an antistress response (see *Oxytocin-opioidergic Hypothesis* in Chapter 6), producing numerous short-term and long-term physiological benefits conducive to calming and growth (Uvnäs-Moberg, 1997a)—high priorities of early puppyhood. Rhythmic stroking, warmth, and vibratory stimuli have been shown to produce a highly beneficial release of oxytocin

(Uvnäs-Moberg, 1998). The postnatal release of oxytocin produced by repetitive massage-like stroking (strokes lasting 1.5 seconds) has been shown to have long-term beneficial effects on blood pressure and irritability thresholds (Lund et al., 2002), appearing to counter the adverse effects of prenatal stress in rats (Holst et al., 2002). Such stimulation has also been shown to exert an anti-anxiety effect (Windle et al., 1997), and repeated exposures to oxytocin-releasing stimulations help to restrain HPA-system activity (Peterrson et al., 1999). These findings strongly support the hypothesis that supplemental rhythmic massage and tactile stimulation may be of significant benefit for promoting an adaptive response to stress.

Exposure to Separation

Distress vocalization in response to separation from mother and littermates rapidly increases after 21 days and peaks at 31 days (Gurski et al., 1979). Elliot and Scott (1961) found that repeated early exposure to separation distress progressively enhanced the puppy's ability to cope with isolation in a strange place (see *Social Attachment and Separation* in Volume 2, Chapter 2). Puppies exposed to weekly 10-minute periods of separation beginning at week 3 and continuing through week 12 exhibited the least amount of distress when tested at week 12 in comparison to puppies first exposed to separation at weeks 6, 9, and 12. Twelve-week-old puppies that had not been previously exposed to separation were found to be highly reactive to isolation, showing a steady increase in separation distress over the 10-minute test period. Puppies previously exposed to separation appeared to have learned how to cope more effectively with it, exhibiting much less distress. Although puppies can habituate to isolation as the result of repeated exposure to uneventful separations, this capacity appears to develop slowly and may not be functional until a puppy is 7 or 8 weeks of age (Hetts, 1989). Interestingly, in contrast to Elliot and Scott's findings, Hetts found that 12-week-old puppies, despite a previous lack of exposure to separation, showed a distinctive pattern of inhibition involving a decrease in distress vocalization and activity when isolated for the first time at week 12. Further, when tested at week 16, these puppies not previously exposed to isolation from weeks 4 to 12 produced significantly fewer distress vocalizations than did puppies repeatedly exposed to isolation consisting of 10 minutes/day for 6 days a week over that same period. These findings obviously conflict with those of Elliot and Scott, suggesting the need for additional research to resolve the question concerning the optimal procedure for exposing puppies to separation.

Hetts' findings seem to suggest that separation distress is relatively immune to habituation effects from week 4 to week 8, which is interesting with respect to onset of weaning. The finding that naive 12-week-old puppies showed less distress vocalization and activity during the first 30 minutes of testing at week 12 than did puppies previously exposed to isolation is consistent with an emergent inhibitory fear response associated with a strange place. Under natural conditions, distress vocalizations might attract danger, making its inhibition an appropriate response given the circumstances and the puppy's age. For example, if feral, a 12-week-old puppy might be left alone for long periods at a relatively unfamiliar rendezvous site without the mother's protection, requiring that it remain quiet and inconspicuous until her return. A genetically programmed timetable for a reduction in distress vocalization at around week 12 would make evolutionary sense. The lack of a comparable or better reduction in distress vocalization in the group of puppies repeatedly exposed to isolation might be attributable to an habituation effect reducing the puppy's fear of the isolation situation, thereby causing it to feel more relaxed to express its discontent. However, these puppies did show a significant reduction in distress vocalization as the result of habituation from week 8 to week 12, whereas a third group of puppies, isolated for 1 hour/week over the 8-week period, did not show evidence of a reduction in distress vocalization and showed no difference with respect to activity level in comparison to the frequently and repeatedly exposed group. This finding seems to indicate that while 1 hour of exposure was sufficient to habituate fear toward the isolation situation,

it was not sufficient to habituate separation distress.

Finally, Hetts' results suggest that a puppy's ability to cope with separation distress may significantly improve as it matures, a finding that lends some credence to Slabbert and Rasa's suggestion that adoption delayed until week 12 is less stressful and yields health benefits (Slabbert and Rasa, 1993) (see *Adoption and Stress*). Perhaps, in the case of households in which a puppy will be exposed to a great deal of daily separation and isolation, delaying adoption to week 12 might be preferable to adoption during week 7, but only if the preadoption situation provides the puppy with adequate socialization and training in preparation for its future home life (e.g., house training).

Punishment and Separation

Increased attachment and inordinate separation distress may paradoxically result from excessive disciplinary interaction. Fisher (1955) found that puppies that were exposed to a combination of social indulgence and punishment exhibited the most pronounced dependency and proximity-seeking behavior (see *Separation Distress and Coactive Influences* in Volume 2, Chapter 4). A pattern of excessively punitive and indulgent interaction occurring early in the socialization process may predispose a dog to show social conflict and reactive behavior in adulthood. Such interaction may sensitize pathways associated with threat-avoidance behavior and produce a conflict-laden attachment with the owner. During punitive interaction, the owner, otherwise a source of comfort and safety, temporarily becomes a serious threat from which the puppy seeks protection, often by soliciting it from the owner in the form of fearful submission displays—a social conflict dynamic that may be permanently codified into a problematic stress-antistress mosaic of neuropeptide activity (see *Developmental Adversity and Adjustment*). Later, under the influence of social transactions involving emotional exchanges or loss at separation, these stress-antistress factors may express themselves in adult coping responses that may include persistently intrusive and excitable behaviors, on the one hand, and intensely emotional, provocative, and reactive behaviors, on the other. Excessively indulgent and punitive interaction contributes to the intensification of a problematic and conflicted attachment process. Scott (1992) points out the potency of both attractive and aversive interaction to facilitate attachment by way of a general hypothesis:

> The occurrence of any strong emotion, whether pleasant or noxious, will speed up and intensify the process of attachment. (84)

Overattachment involving excessive indulgence and punitive interaction may result in a developmental fixation and a regressive dependency and intolerance for separation from the owner, or foster an adversarial and conflict-prone relationship, perhaps setting into motion social dynamics conducive to adult aggression problems, or both. Alternating between intense emotional stimulation of hedonically opposite and incompatible valences, especially when delivered indulgently and noncontingently (e.g., belated punishment) is highly destructive and without justification. Ultimately, the degree of harm resulting from such treatment depends on hereditary factors and subsequent behavioral support. Dogs genetically expressing low fear or anger thresholds may be particularly vulnerable to the lasting effects resulting from mistreatment.

Attachment and Separation Problems: Puppies

Adoption and Stress

Sudden changes in routine (e.g., amount of attention, exercise, or restriction) that a dog is accustomed to receive may produce significant biological stress, perhaps inducing emotional and behavioral disturbances in predisposed dogs. For example, moving a dog, accustomed to sleeping in a crate in the kitchen, to a bedroom may result in intense restlessness and inability to calm down. Some dogs pace, pant, and drool, appearing highly distressed by the change. Although puppies appear to be much more resilient and adaptable than adult dogs to change, it is reasonable to assume that separation-related distress

associated with adoption may produce lasting adverse effects if not properly managed. The timing of adoption and placement of puppies may also have a strong effect on development, health, and behavior. Slabbert and Rasa (1993) found that German shepherd puppies removed from their mothers at week 6 thrived poorly and showed a significantly greater risk for disease and mortality than did puppies naturally weaned by their mother between weeks 7 and 8. They also exhibited significant behavioral deficits: "Puppies weaned before 7 weeks of age are noisy and nervous. These seem to become fixed characteristics of the dog for life" (5).

Puppies allowed to stay with their mothers through week 12 were healthier, gained more weight, and appeared better adapted. However, the significance of early adoption on the incidence of SDS has been questioned. For example, Flannigan and Dodman (2001) were unable to detect a correlation between early adoption (earlier than 7 weeks of age) and an increased risk of developing separation-related problems in comparison to other behavior problems. The authors do, however, leave open the possibility that puppies adopted at an early age may be generally more susceptible to behavior problems. Deferring adoption until week 12 conflicts with standard practice, and any potential benefit of delayed adoption would depend on the quality of socialization, habituation, and training taking place during those critical weeks while a puppy remains under the breeder's control. Ideally, a dog destined to become a family companion should be placed at around week 7, based on a number of compelling scientific considerations, practical management issues (e.g., house training), and social bonding benefits (see *Secondary Socialization (6 to 12 Weeks)* in Volume 1, Chapter 2). As previously discussed (see *Exposure to Separation*), an exception to the week 7 rule of thumb rule might involve puppies destined to households in which they will be exposed to lengthy daily separations and isolation.

From a familiar environment and social setting, a newly adopted puppy is thrust into quite a different situation of unfamiliar sights, sounds, smells, and social demands. In addition to environmental strangeness, this new situation is probably governed by rules and expectations that sharply conflict with previous learning and social experiences. Some dogs may never fully overcome this momentous loss of filial kinship and sense of security. In combination, the abrupt loss of affiliative bonds and loss of place attachments may create a highly stressful state of disorientation and confusion, perhaps verging on helplessness when coupled with adverse rearing practices (see *Adverse Rearing Practices That May Predispose Dogs to Develop Separation-related Problems* in Volume 2, Chapter 4). Helplessness and excessive dependency are natural behavioral corollaries of excessive confinement and punishment during puppyhood.

Although many factors play a role in the development of separation-related anxiety and panic in adult dogs, the manner in which this original separation trauma is managed probably plays some role in predisposing vulnerable puppies to develop the adult disorder or helping to prevent it. Obviously, there is a natural tendency for puppies to rely on previously acquired behavior patterns in an effort to cope with the demands of family life. Some of these behaviors are conducive to a harmonious transition, while others may set the groundwork for significant interactive conflict and potential problems. Despite the potential pitfalls and difficulties, it is truly remarkable how well most puppies navigate the transition into family life, underscoring the average puppy's high degree of behavioral and emotional flexibility. Clearly, the young dog is very adaptable and, when problems do occur, more often than not they are the result of improper training or mismanagement. With these considerations in mind, it makes sense to provide newly adopted puppies with careful transitional handling and training in an effort to reduce the amount of stress associated with adoption. The first step in making a successful transition is to recognize that the puppy is probably experiencing significant stress and disorientation, despite outward signs that may seem to indicate otherwise. The energetic and rough efforts of children to play with a new puppy are probably not beneficial. What the puppy needs during the transitional period is gentle handling, nourish-

ment, and quiet surroundings, especially for the first few days.

Coping with Stress at Separation

A significant source of emotional distress for puppies is associated with the strain and upset elicited by separation and confinement (Borchelt, 1989). The average puppy has not had very much prior experience with being left alone and may not cope well with even brief periods of separation. For many puppies, learning to cope with loneliness and isolation without excessive worry and distress is a hard lesson for them to master, and their success will depend on the patient guidance and support of understanding owners. Initially, the puppy should be allowed to sleep in the bedroom, and only gradually moved to another part of house—if such an *unnatural* arrangement is necessary. If available from the breeder, a familiar soft toy or towel possessing the odor of the mother may help to pacify the puppy at bedtime and when left alone during the daytime. One possible method for breeders to explore is to associate the mother with a distinctive dilute odor throughout the nursing period. The odor can then be bottled and given to the owner to spray on bedding and so forth, perhaps providing some relief to the puppy at times when it needs to be left alone. Alternatively, the breeder may wipe the mother from head to toe with a damp cloth and rinse it in a quart of spring water. Wiping the area of the intermammary line may be particularly useful, since it is reportedly associated with the production of appeasing pheromones in lactating dogs (see *Dog-appeasing Pheromone*). The water can be stored in a spray bottle (refrigerated) and applied to bedding and locations where the puppy is confined.

Confinement

Confinement is useful for facilitating early house-training efforts, to prevent household damage, and for the sake of the puppy's safety in the owner's absence. This will require that the puppy be introduced to some amount of crate confinement. It is important that the puppy form a positive place attachment with the crate. The crate should be equipped with soft toys (stuffed animals and knotted towels) and blanketing—all of which may help to pacify and relax the puppy. In addition, some puppies may benefit from a mirror securely attached to the outside of the crate or nearby wall. Although most puppies can be trained to accept crate confinement without too much trouble, some may rebel despite the most patient and systematic efforts to desensitize them. Such persistent and demanding puppies may find crate confinement highly frustrating and vigorously protest against it. It is important to exercise careful judgment here and not mistake frustrative protests against confinement as separation-related panic. Vocalizations associated with separation-related panic are not under the same degree of voluntary control as vocalizations exhibited by difficult and frustrated puppies. In such cases, exposure to crate confinement might be carried out via a folding pen that is gradually made smaller, while the crate is made attractive and comfortable.

Many crate-training problems can be avoided by slowly introducing such confinement through gradual steps (see *Crate Training* in Chapter 2). Finally, regardless of the reasons for confining a puppy, it should be done in a part of the house that is familiar to the puppy (e.g., the kitchen or bedroom). The highly questionable practice of isolating the puppy or family dog in the basement or garage during daily absences is associated with an increased risk of heightened separation distress and panic.

All normal puppies are stressed by separation and may vent their displeasure through intense vocalizations aimed at getting the owner's attention or engage in other activities (e.g., chewing baby gates) aimed at securing contact. Allowing a puppy to persist in such stressful isolation behavior may inadvertently potentiate separation-distress reactions. On the other hand, routinely responding to such protests with affectionate reassurance or by releasing the puppy from confinement may only serve to reinforce such unwanted behavior. Diverting the puppy with a treat or sound (e.g., a squeak) and requiring that it remain quiet for some brief period before releasing it is probably better than just rescuing it at such

times. Although the puppy's sensitivity to isolation usually decreases as it matures, it is still important that the puppy learn how to cope with such situations without experiencing excessive distress. This is usually accomplished through graduated exposure and desensitization. Training a puppy to accept isolation is accomplished by scheduling opportunities for social contact, exercise, and play in exchange for short periods of confinement and separation—a process that is carried out concurrently with early crate training. Separation training instructs the puppy to anticipate regular attention and contact based on contingent waiting and quiet behavior. Although intensive affection, stroking, massage, and feeding by hand may help to counter the stress associated with adoption, social contact should gradually approximate the amounts of attention and contact that will likely be provided to the dog as an adult.

Graduated Departures

Graduated exposure to brief and nonthreatening separation experiences may help to immunize a puppy against the stressful effects of more lengthy separation (Voith, 1980; Marks, 1987). Training a puppy to accept limited exposure to separation can be accomplished by gradually exposing it to increasing periods of crate or pen confinement. The crate or pen should be placed in a room where the puppy is left when the owner is away from home. Once the puppy can tolerate being left alone in the room, the next step is for the owner to begin leaving the house for varying lengths of time, thereby gradually increasing the puppy's tolerance for owner departures and absences. The goal of such training is to help the puppy to anticipate the owner's return optimistically while systematically reducing its aversion to being left alone. These safe and relaxed planned departure activities help the puppy to learn that separation is temporary and that the owner's eventual return is certain. Gradually, the puppy develops more positive expectations about separation events, learning to tolerate departures and to wait patiently for the eventual return of the absent owner.

From the very beginning, safety stimuli or bridges should be paired with every safe departure experience. Safety stimuli can be easily established by associating short, nonanxious departures with an auditory, visual, or olfactory stimulus (e.g., a scent associated with the mother or used during massage). Safety stimuli appear to give the puppy some sense of security when it must be left alone, perhaps by forecasting the owner's eventual return or by evoking conditioned associations of comfort and safety. The goal is to establish a positive association between safe separation experiences and ambient contextual stimuli. Also, just before leaving, the puppy is given a highly prized chew item made available primarily at such times (e.g., a hollow rubber toy slathered with peanut butter). With the puppy distracted by the toy, the owner turns on a radio or television and light and exists the room. After a brief separation, the owner returns, turns off the radio or television and light, goes to the puppy, and retrieves the chew toy. At the conclusion of a safe departure, the puppy is given a brief period of tug or fetch play, especially if signs of building stress are evident.

The aforementioned pattern of departure and return is repeated again and again, increasing and randomly varying the duration of departures. Care should be taken not to proceed too quickly, and closely observe the puppy for any signs of distress. If the puppy becomes distressed, the handler should return to a previously successful step and try again. In the case of highly sensitive and reactive puppies, the process of introducing safe and relaxed departures might begin by merely scooting back a foot or 2 before returning to the puppy to reward it. Standing up and walking 2 or 3 steps back and waiting for a 5 or 10 seconds before returning might be the next step, followed by a variety of similarly gradual departure steps organized to prevent the puppy from becoming distressed. Sometimes training the puppy to sit-wait and down-wait while in the crate can be useful in the context of planned departure training, gradually training the puppy to wait for longer durations, at greater distances, and involving progressively more difficult departure exposures (e.g., going around a corner, into another room, and finally outdoors). Varying the duration of separation by inter-

spersing short and long durations randomly is useful [e.g., 30 seconds, 15 seconds, 10 seconds, 1 minute, 20 seconds, 5 seconds, 45 seconds, 1 minute 30 seconds: variable duration (VD), 35 seconds]. The first 20 minutes of separation for a puppy are the most sensitive, with proper confinement training and desensitization focusing on the first 10 to 30 seconds providing a stable foundation and anchor for subsequent counterconditioning efforts. It is not necessary, therefore, to spend long hours desensitizing a puppy to separation, but to concentrate on the first minute or 2, gradually building up to 20 to 40 minutes. As the puppy progresses, add more varied and realistic departure experiences to the program, including picking up keys, slipping on shoes, putting on an overcoat, picking up a briefcase, and so forth (see *Graduated Departures and Separation Distress*).

Planned Separations

In addition to brief, graduated exposure to separation, other benefits may be obtained by exposing a puppy to more protracted periods of safe separation. Poulton and colleagues (2001) have reported that late-adolescent separation anxiety in children is negatively correlated with the number of overnight hospital stays away from home in early childhood, with more overnight stays away from home being associated with a reduced risk of separation anxiety. Also, as one might expect, the longitudinal study found that children exposed to planned hospital stays experienced fewer symptoms of separation anxiety in late adolescence than did counterparts exposed to unplanned hospitalization. The use of dog day care and overnight stays away from home in a safe and supportive environment may provide additional inoculation against adult SDS. Such recommendations should be seriously considered in the case of puppies showing evidence of excessive distress when left alone.

In the case of puppies that need to be left confined to a crate (e.g., needing such confinement for house-training purposes), with a high probability that heightened distress will occur while the owner is absent, a second crate might be used transitionally to avoid associating stressful arousal with the safe crate (Voith, 2002). In preparation for such departures, the puppy should be given a high-value chew item and put in the crate for at least 5 minutes before leaving. A fragrance such as lavender or chamomile might be sprayed initially and then diffused by means of a diffuser and aquarium pump (see *Taction and Olfactory Conditioning*). Although the author has not yet evaluated the usefulness of dog-appeasing pheromone, it is reportedly helpful in the management of distress at separation in puppies and dogs (see *Dog-appeasing Pheromone*).

During stressful habituation exposures to separation, the owner should avoid returning to the puppy while it is still aversively aroused. Instead, for example, upon returning from an errand, the owner should check first and make sure that the puppy is not vocalizing before entering the house. If the puppy is vocalizing and does not stop, the owner might call the home phone with a cell phone, perhaps momentarily distracting the puppy, whereupon the owner should enter the house and initiate a brief period of attention training (i.e., orienting response to a squeak followed by a click and treat), feeding the puppy through the crate door, but refraining from immediately letting the puppy out. As the puppy shows signs of calming, it is released and tossed a ball or engaged in sit and sit-stay training with a brief attending response, whereafter it is transitioned to the scented safe crate or confinement area. The foregoing method helps to control aversive arousal, enhances attention and impulse control during greetings, and associates opponent relief and relaxation produced by the owner's return with the safe crate and the olfactory safety signal (OSS). Habitually using the cell phone to call home prior to entering the house can establish a potent conditioned safety signal by association with the owner's homecoming. Alternatively, a remote doorbell and the sound of the garage door opening can be used to serve a similar purpose. The sound of the garage opening, the doorbell, and the phone are naturally conditioned in association with increased social activity and transition and can be used in a variety of creative ways as

diversionary stimuli to manage puppy and dog behavior.

Miscellaneous Recommendations

Taking measures to reduce or prevent separation distress is an important aspect of puppy rearing. In addition to the aforementioned recommendations, the following list of suggestions should be considered:

- Avoid excessively emotional interaction that might lead a puppy to become overly attached and dependent. Although a young puppy needs a great deal of attention and affection, the character of this attention need not be indulgent. Constructive interaction involving various training activities, walks, and instructive play is much better than just providing gratuitous affection and unearned treats.
- When leaving a puppy alone for extended periods, the puppy should be confined to well-socialized part of the house (e.g., the kitchen). Ideally, the puppy should be restrained in an exercise pen equipped with an open crate made comfortable with bedding. The floor of the penned area should be covered with several layers of newspapers for the inevitable accidents. *Do not restrict water.* Make an audio tape of the puppy's reaction to separation, thereby providing some baseline information about the puppy's response to it and improvement (or not) over time.
- Avoid overemotional departures and homecomings. Approximately 5 to 10 minutes before leaving the puppy, it should be placed in the pen and given a highly desirable chew item that is not provided at other times. Giving the puppy periodic treats during this time can help calm it. Puppies appear to benefit from the presence of a towel richly scented with the owner's body odor. Also, it may be useful to direct the puppy's attention to the towel as an object of play and contact when the owner returns home. Puppies prone to become overly aroused should receive 1 to 3 minutes of massage just before being confined and then again after homecomings.
- Avoid punishing a puppy for destructive behavior or elimination occurring during absences. Such punishment will not impact beneficially on the misbehavior and may make the situation worse. In general, aversive training methods should be minimized or avoided (if possible) during the transitional period immediately following adoption.

As a puppy develops, it will naturally become more confident and independent, with the puppy appearing to develop improved abilities to cope with safe separation exposure between weeks 8 and 12 (Hetts, 1989). With maturation, separation reactions usually decrease in intensity, unless—because of excessive frustration, inappropriate punishment, or inadvertent reinforcement—the puppy learns to persist in such undesirable behavior. With maturation, reactive separation behavior usually moderates as a secure and balanced social relationship is established between the owner and the dog. However, as the result of adverse interaction (e.g., social frustration, inappropriate punishment, or inadvertent reinforcement), the dog may form a problematic attachment and express persistent separation-related distress when left alone. The social competence provided by structured integrated compliance training, in combination with habituation and graduated exposure to separation events with counterconditioning, appears to exert an ameliorative and preventive effect on separation distress. However, extensive early socialization and training efforts away from the home may not be beneficial. According to Bradshaw and colleagues (2002), extensive exposure to varied social contacts at approximately month 3, involving persons not belonging to the family, strangers, or children, may predispose puppies to exhibit problematic separation-related behavior between months 6 and 9. Conversely, extensive social exposure between months 6 and 9 appears to exert a protective influence by reducing the risk of subsequent separation-related behavior. These findings suggest the possibility that socialization with varied people and situations away from the home in early puppyhood (e.g., puppy socialization classes) may not be beneficial with respect to separation-related adjust-

ments, whereas added separation-related benefits may be obtained as the result of attending group training classes and providing diversified socialization experiences after month 5 or 6.

McBride and colleagues (1995) have reported that dogs (N = 44) rehomed from an animal shelter between 6 and 12 months may be at greater risk of developing separation-related behavior problems than dogs adopted in other age groups. Perhaps, during this important developmental transition between puppyhood and adulthood, there exists a period of increased vulnerability to the emotional effects of attachment and separation. However, another possible association may exist that should receive additional research. This time frame is commonly associated with neutering, a procedure that has been implicated as a potential risk factor in the development of separation problems. Flannigan and Dodman (2001) have found that sexually intact dogs were three times less likely to exhibit separation problems than neutered counterparts (male and female). With respect to the influence of sheltering on the incidence of separation-related problems, in addition to the traumatic loss of attachment objects suffered by the relinquished dog, the sheltered dog may subsequently form strong place and social attachments with the shelter environment and workers. In addition, the daily stimulation of cleanup, feeding, and other care activities, the presence of other dogs, periodic visits, and exercise opportunities may significantly contrast with the humdrum loneliness of the adoptive home environment. Sheltered dogs appear to form rapid attachments, requiring as few as three meetings with a stranger consisting of 10 minutes each to show a significant increase in attachment behavior (Gácsi et al., 2001). A shelter dog may be sensitized in various ways to attachment processes that predispose it to become emotionally vulnerable when left alone.

PART 2: SEPARATION DISTRESS AND PANIC: TREATMENT PROCEDURES AND PROTOCOLS

Attachment and Separation Problems: Adult Dogs

Most dogs appear to accept daily exposure to long periods of separation without showing excessive distress. Separation-reactive dogs, however, exhibit a distinct and persistent pattern of generalized arousal, protest, or excessive worry when left alone. SDS is identified by a cluster of diagnostic signs and symptoms involving a variety of biobehavioral modalities, including appetitive, oral, vocal, motor, eliminative, and physiological changes (Table 4.1).

Diagnostic Signs of Separation Distress

Few dogs exhibit all of the aforementioned signs listed, but many show more than one sign, and it is not uncommon for separation-distressed dogs to exhibit several of the behavioral signs of distress whenever they are left alone. Owners should be encouraged to maintain a behavioral journal, including a record of separation-related behavior in order to produce an objective assessment of the benefits of training and behavior therapy (Figure 4.6).

Table. 4.1. Diagnostic signs of separation-distress syndrome (SDS)

Excessive attachment (clinging behavior)
Predeparture restlessness
Separation-distress vocalization (e.g., barking and howling)
Destructive behavior only when left alone
Self-injurious behavior
Urination and defecation only when the owner leaves
Separation-related loss of appetite
Excessive greeting behavior

COMMENTS:

FIG. 4.6. Daily separation-distress chart. The day of the week is checked and a brief note concerning the separation-related behavior is recorded (time of day, location, object, and duration, and so forth).

Appetitive Signs

Separation-distressed dogs are usually anorexic. Some will even ignore a fresh beef bone or other highly prized food items until the owner returns. Separation-induced anorexia can be very problematic when it involves dogs being boarded or hospitalized.

Oral Signs

Many separation-distressed dogs are destructive when they are left alone. Among 200 dogs presenting with separation-related problems at Tufts Animal Behavior Clinic, destructive behavior was the most common complaint, with 71.7% of the dogs showing some form of household destructiveness when left alone (Flannigan and Dodman, 2001). These findings roughly correspond to those reported by Voith and colleagues (1997), in which the most common complaint associated with separation anxiety was destructiveness, followed by excessive vocalization, elimination, aggression, and overactivity. McCrave (1991) has differentiated destructive behaviors occurring with separation distress from destructive behaviors associated with other common etiologies. She has noted that separation-related chewing is typically directed toward points of egress, whereas playful destructive behavior is directed toward items "that are fun to toss or shred" (252), e.g., pillows, furniture cushions, and paper. These latter items are frequently targets of separation-distressed dogs as well, requiring careful analysis of the context and the presence of other signs to determine whether the destructive appetite is due to separation or other causes (see *Assessing Separation-related Problems* in Volume 2, Chapter 4). Separation-reactive dogs often scratch doors and dig at carpets in front of doors. Miller (1966) aptly describes this behavior as *barrier frustration*: "Frustration creates tension and the dog releases this tension, causing a problem like chewing. The single greatest frustration and tension builder is found in barriers, usually the door" (104). In addition to points of egress, destructive chewing is directed toward a wide variety of socially significant objects. In some cases, the chew object chosen by the dog appears to provide a symbolic link with the absent owner. Besides clothing, shoes, books, the television remote, pillows, and the owner's bed, separation-reactive dogs may chew on woodwork, curtains, furniture—almost anything that it can sink its teeth into, except, ironically, the chew toys that have been left for such purposes. Such compulsive chewing activity appears to provide an outlet for anxious feelings. But because the dog often chooses personal belongings as objects to gnaw on, the owner is often convinced that the dog is misbehaving out of spitefulness (Lindell, 1997).

Vocal Signs

Another common complaint associated with SDS is separation-related barking. Although barking is not the most common complaint, it is extremely common among dogs becoming reactive at separation. Voith and colleagues (1997) reported that 90% of separation-anxious dogs (N = 36) barked when left alone, with 80% engaging in destructive behaviors and 55% exhibiting elimination problems. Owners of such dogs are often prompted to seek help as the result of a citation or a neighbor's complaint. Sustained barking and howling are vocalization variations that many separation-reactive dogs exhibit—some to an astonishing extent. It is amazing how long a dog can bark and howl without stopping. Many owners return home daily to find their dog soaked with slobber from hours of agitated barking and panting.

Motor Signs

Many dogs become overactive at separation, with nervous pacing and bursts of frantic motor and exploratory activity occurring periodically during the day.

Eliminative Signs

In cases where the dog exhibits normal eliminatory control while the owner is at home, but loses control only when he or she leaves the house or denies contact to the dog, separation distress should be considered as a putative causal factor underlying the problem. Flannigan and Dodman (2001) reported that 28.1% of dogs with separation anxiety

showed some form of inappropriate elimination when left alone.

Physiological Signs

Separation-distressed dogs may exhibit a variety of signs indicating pervasive autonomic arousal, including trembling, panting, increased heart rate and, less frequently, profuse salivation or diarrhea.

In addition to the identification of emotional and behavioral signs of separation distress, dogs with SDS should be screened for phobias, especially noise and storm phobias. Flannigan and Dodman (2001) found that nearly half of dogs with separation-related problems also exhibit evidence of noise phobia. In cases where SDS occurs comorbidly with a phobia, the successful resolution of the separation problem requires that both problems be addressed (see *Prognostic Considerations* in Chapter 3).

Preliminary Considerations

Owners of dogs with separation-related behavior problems must first be convinced that their dog's misbehavior is not motivated by spite or vindictiveness. This is not always easy for one reason or another. Some owners may simply not want to get bogged down with behavioral explanations that portend difficult and time-consuming training efforts; they may have little patience in reserve and want immediate results. Others simply cannot rise above a heartfelt conviction that their dog is punishing them. An astonishing number of dog owners adhere to the belief that dogs often misbehave to spite the owner. In a large study, New and colleagues (2000) found that 48.3% of persons relinquishing their dogs to shelters held that dogs will misbehave to spite their owners, with nearly an equal percentage of owners (44.3%) with a dog living in the household indicating a similar belief concerning the spiteful motivation of canine misbehavior. The implications of spite and vindictiveness are distracting and misleading, but many separation-reactive dogs do appear to be more angry than anxious, appearing to protest at being left alone. Protest is a common behavioral sign of canine separation distress, resulting in persistent vocalization, increased motor activity, and destructive behavior (see *Separation Distress and Coactive Influences: Frustration* in Volume 2, Chapter 4). This situation is compounded when strong external pressures are demanding that the owner achieve results quickly or face dire consequences. Dogs are rarely brought for treatment of separation distress without some pressing behavioral complaint, including neighbor complaints, threats of eviction, or costly citations. What many of these owners want is a ready and easy means to suppress their dog's misbehavior—not a psychological explanation for it. Other owners welcome a scientific understanding of their dog's separation problems and willingly face the prospects of a daunting training process as a challenge and responsibility.

Every situation is a bit different, and it is of immense importance that problems involving separation distress be approached with an appreciation for each case's unique characteristics. Failure to take such matters into consideration will invariably impact adversely on compliance and the overall effectiveness of training efforts. Behavioral counseling is a pragmatic process based on a fluid dialogue between the trainer and the owner, often requiring compromise on minor points in order to build overall support and enthusiasm for the program. An owner's cooperation and confidence is won through a process of gradual persuasion and logical demonstration—not polarizing confrontation and criticism. Pressure tactics—no matter how accurate and brilliant—serve little purpose but to cause the owner to feel resentment toward the trainer. An experienced trainer listens to the owner's needs and assiduously avoids judgmental polemics. The cynopraxic trainer is a mediator showing the owner how to improve the situation, while avoiding narrow and one-sided prescriptions that the owner cannot accept or will not carry out. Consequently, wherever possible, the training program must be modeled to conform to the owner's needs and expectations.

Very few owners are able to implement the current planned-departure protocol for the treatment of separation distress in its entirety or apply it with the sort of diligence that the

procedure requires to optimize success. The underlying premise of such training is based on systematic desensitization and graduated counterconditioning. The owner is instructed to leave the dog for progressively longer periods, starting with a few seconds and gradually building the dog's tolerance for longer and longer periods of separation. While undergoing separation desensitization, the owner is instructed never to leave the dog alone under circumstances that may evoke separation distress or panic. This most central requirement is often impossible for owners to comply with, since it may entail considerable expense (e.g., day care or pet sitting) or inconvenience. Occasionally, a neighbor or relative will volunteer to watch the separation-reactive dog while it is undergoing training, but this is usually the exceptional situation rather than the rule.

Effective behavior therapy requires a high degree of competence in the application of a highly technical and exacting methodology. Desensitization procedures, in particular, assume a psychological understanding that may be natural for an applied dog behaviorist, but are often arcane and difficult for a dog owner to master. Most owners presenting their dogs for behavior therapy do not possess the self-discipline or understanding to adhere methodically to a behavioral plan. Describing the most general aspects of the process is easy, but the actual mechanics involved require the development of special skills and knowledge that may not be realistically attained in short-term counseling. Surely, many of the required skills cannot be fully mastered after a single session of counseling, but that is precisely what is often expected of the client-owner by the busy dog behavior therapist. This shortcoming of "brief therapy" may represent a serious danger for the owners of aggressive dogs who are expected to perform advanced behavior-therapy procedures after a single session of counseling. This situation can be somewhat mollified by supplementing verbal instructions with relevant reading material. Many articles and pamphlets have been written on the subject in a language that is accessible to the average owner, but few provide the sort of detailed instruction that would help the owner to apply the procedures meaningfully and consistently. Despite these shortcomings, most owners still report good results from the portion of the behavior protocol that they are able to carry out; even a few simple tips over the phone appear to help a great deal in some cases.

In addition to recording a thorough behavioral history, assessing separation distress is assisted by making an audio tape recording of the dog's reaction to separation. Besides monitoring the dog's behavior during a specific time frame and getting a picture of the sorts of things the dog does during separation, such recordings provide a baseline from which to gauge training progress or lack thereof. Although not all separation-anxious dogs bark or howl, a great many do, but even those that do not will often exhibit other signs of agitation that can be picked up by an audio recorder. A motion-activated video recorder can also be extremely useful for assessing separation behavior and tracking a dog's progress (Figure 4.7). Also, the owner should be encouraged to keep a behavioral journal for recording daily training activities and noting the dog's response to behavior-therapy efforts, such as planned-departure training. Records of planned departures should include the date and time, the length of departure, and a brief description of the dog's behavior (Figure 4.8).

FIG. 4.7. Motion-activated remote video system. Inexpensive video devices are available to record a dog's separation activities throughout the day. A motion-sensitive infrared detector turns on a remote VCR and turns it off again after a short period. A similar device could be devised to activate an air-pump odor dispenser and feeder described in Chapter 3 (see *Systematic Desensitization*, Figure 3.5).

COMMENTS:

FIG. 4.8. Planned departure chart.

Behavioral training for separation-reactive dogs involves a variant application of systematic desensitization and instrumental training (Hothersall and Tuber, 1979). Departures are planned and graduated in such a way that the dog progressively learns to anticipate the owner's eventual return without experiencing excessive worry or distress. In additon, more appropriate waiting behavior is systematically reinforced. The systematic desensitization portion of this plan may be superfluous, especially if it is determined that the dog's

separation problems are motivated by frustration and protest. If fear is determined to play a role, then it may be more profitable to identify the fear-eliciting stimulus and desensitize the dog to it first, rather than attempting to desensitize the dog to separation while it continues to remain fearful of the situation. As already noted, in practice systematic desensitization by way of graduated departures is nearly impossible for the average dog owner to carry out. Very few people have the luxury to take two or three weeks away from work to administer a dog's desensitization training. Nonetheless, meaningful progress can be made by performing graduated departures while at home with the dog, counterconditioning predeparture cues, focusing efforts on shaping more appropriate predeparture behavior, and employing various techniques to improve the quality of attachment and interaction between the owner and the dog.

Summary of Behavioral Procedures Used to Modify Separation Distress

Podberscek and colleagues (1999) found that behavior modification without medication was effective for controlling behavior problems associated with separation-related distress. The eclectic program that they recommend involves four phases of therapy (Table 4.2). King and colleagues (2000) have described a similar treatment program used in conjunction with clomipramine, which they divide into these areas of focus:

At-home interaction
- Dog is ignored during greetings until it calms down.
- All forms of retroactive punishment should be discontinued.
- All interaction between owner and dog must be initiated by the owner.
- Attention-seeking efforts by the dog should be ignored.
- Touching and playing with the dog are restricted to interaction on the command and initiative of the owner.
- Dog may sleep in the bedroom at the owner's initiative.

Departure procedures
- The dog is ignored for 30 minutes prior to departure.
- The dog is confined to the location where it must stay for the day 30 minutes prior to leaving.
- The dog is provided with toys and an object impregnated with the owner's scent.
- The owner is instructed to practice false departure routines in which preparations to leave are not followed by the owner actually leaving the house.

Other common treatment recommendations include graduated departures (Voith, 1980; Voith and Borchelt, 1985), involving progressively longer and more realistic departure exposures, muzzling the dog while the owner is away from home (Polin, 1992), and lengthy daily crate confinement (Takeuchi et al., 2000). Muzzling separation-reactive dogs is of questionable value and represents a significant risk of harm to such dogs (e.g., aspiration of vomit and heat exhaustion). Separation-distressed dogs become highly excited, and panting helps to regulate building body and brain temperatures. Restricting the dog's ability to pant may result in it overheating, with devastating results. Also, highly reactive dogs may become virtually obsessed with getting the muzzle off, possibly doing significant damage to themselves in the process. The so-called *denning* method involves the following stages of crate confinement (Takeuchi et al., 2000):

- The dog is confined to its crate continuously for 2 weeks, except for elimination, exercise, and obedience training.
- The dog is confined for an additional 2 weeks except when the owner is at home and awake.
- The dog is confined for an additional 2 weeks only when the owner is away.
- The crate door is left open at all times, permitting the dog to come and go as it pleases.

The use of crate confinement for treating SDS is fraught with dangers and raises a number of welfare concerns. Voith and Borchelt (1985) have criticized the use of crate confinement for treating separation-

related behavior as usually being counterproductive. In addition to persisting in the unwanted separation behavior, dogs confined in crates may severely injure themselves in an effort to escape confinement. When the crate is used, it should be introduced gradually and then faded out again as the dog's behavior improves, making every effort not to allow it to become a steel straitjacket (see *Adverse Effects of Excessive Confinement* in Chapter 2).

The methods used to treat SDS are often very restrictive and highly intrusive with respect to the human-dog relationship. Given the limited behavioral acumen of owners and questionable compliance patterns, it is hard to imagine that owners actual carry out some of the required treatment recommendations. In addition to complexity, procedures that intrude excessively upon the owner's ability to interact, play, and exchange affection with the dog spontaneously may simply be more aver-

TABLE. 4.2. Summary of separation procedures recommended by Podberscek et al. (1999)

Phase 1

Retroactive punishment is discontinued.

The dog is stopped from sitting on a lap or furniture when owner is nearby.

The dog is prevented access to the bedroom by baby gate first and then by closed door.

Gratuitous treats are discontinued.

Only the owner initiates interaction with the dog.

The dog's solicitations for attention are ignored.

Interaction between the owner and dog ceases 1 hour prior to departure.

When ready to depart, the owner waits an additional 10 to 15 minutes before leaving the house.

The dog is confined 20 to 30 minute before departure.

The dog is provided with clothing imbued with the owner's scent, given chew toys that are not otherwise available, tape recordings of owners voice are switched on, and the dog is ignored when the owner leaves the home.

Upon returning home, the owner should change clothing and wait 5 to 10 minutes before releasing the dog from confinement.

The dog's greeting behavior is ignored.

Phase 2

The dog is exposed to progressive and varying periods of separation from the owner while it is at home and awake.

The dog is separated by a door or gate (if separation by closing a door stresses the dog).

The dog is prevented from following the owner around the house.

The dog is prevented access to the upstairs (bedroom) during the day.

Phase 3

The dog is gradually removed from proximity to the bedroom at night and required to sleep in areas progressively closer to the area where the dog is confined during the day.

Phase 4

Predeparture cue desensitization and scrambling are used, e.g., picking up keys, putting on shoes or outdoor clothing, and setting burglar alarm, but not actually leaving the dog.

sive to the owner than the problem itself. In this regard, Takeuchi and colleagues (2000) found that more instructions were not necessarily associated with increased therapeutic benefit. In fact, owners given fewer than five instructions reported significantly better improvement in their dogs' behavior than owners given more than five instructions. Owner compliance was not a significant factor in the outcome of treatment. The significance of the study is hard to pin down, though, since owners who received more instruction may have presented a more severe and intractable problem in the first place. Nonetheless, a possibility exists that owners simply became progressively confused with more instructions or more inclined not to comply.

Aside from social intrusiveness, the implementation of common animal behavior-therapy procedures often involves significant changes in routine and restriction taking place over a very brief period. Stephens (1980) has suggested that abrupt changes in the direction of increased restriction or greater freedom may produce psychological stress, perhaps inclining some sensitive dogs to develop emotional and physiological disturbances. Dramatic loss of attention, contact, and freedom of movement may produce pronounced stress in already reactive separation-distressed dogs. Highly intrusive and restrictive methods of therapy may reduce undesirable behavior by generally shutting the dog down and thereby elaborating a generalized inhibitory state incompatible with separation-related excesses and distress: depression. The detachment process often recommended may not significantly alter a dog's attachment levels, as much as simply depressing the dog by the abrupt change in routine, social loss, and anxiety: previously predictable social interaction is suspended and replaced with physical and rule-based barriers designed to disrupt or prevent normal contact comfort and attention. The influence must certainly be destabilizing for highly attached and insecure dogs. To make therapeutic recommendations effective and humane, changes involving social loss and increased restriction should be implemented gradually and only after other less intrusive methods are carefully considered or tried. The keys to successful behavior therapy are simplicity and respect for the human-dog bond.

Crate Confinement

Despite the dangers and risks involved, crate confinement may prove to be a necessary part of the management of separation-distressed dogs, especially in cases involving destructive problems. Although increased anxiety or frustration may be initially evoked by the introduction of the crate, it is often an unavoidable part of the separation training process. The key here is to introduce the crate gradually together with the provision of comfort objects and appetizing toys over several days (see *Crate Training* in Chapter 2). Treats and toys can be put inside the crate in hopes of tempting the dog to explore it. In addition, the dog can be fed in front and later inside of the crate. In some cases, food is given to the dog only when the owner is about to leave, thereby compelling it to eat while alone and in the crate. Frozen rice balls containing turkey burger and kibble may be useful for this purpose. Rubber toys can also be stuffed with moist food and frozen.

Once the dog is entering the crate on its own accord, the door can be closed for brief periods while giving it treats from the outside. As the dog learns to accept crate confinement by freely entering it, a signal can be established to control the behavior (e.g., "Crate" followed by a hand movement similar to the one used to toss a treat inside the crate). Next, the dog should learn to enter and lie down in the crate for varying lengths of time. These initial exposures to crate confinement should involve a close association with the owner. The owner may lie down next to the dog while it is crated and periodically pet or feed the dog treats. These initial nonexclusionary exposures to crate confinement help the dog to form a positive place attachment toward the crate. As training progresses, the crate will gradually become a place of security and crate confinement a safety signal predicting the owner's eventual return. The crate also offers an effective response-prevention strategy in which the undesirable destructive behavior is blocked while other counterconditioning efforts are carried out. Once the dog becomes

better adapted to being left alone and the risk of destructiveness is reduced, crate confinement can be gradually faded out and the dog given more freedom to move about in the safe room.

The air-pump odor dispenser and feeder described in Chapter 3 (see *Systematic Desensitization*, Figure 3.5) can also be used to facilitate planned-departure training in separation-reactive dogs. The air pump can be used to deliver odor only or food only by clamping the tubing at appropriate points. Food-only delivery can be accomplished by completely closing the three-way valve. A remote switch can be used for remote activation. The presentation of the odor (e.g., orange or lemon-orange mixture) with safe departures and returns of the owner will gradually cause it to become an OSS. When the dog must be left alone for periods that exceeds its tolerance and is likely to result in high levels of distress, the odor should not be presented. The odor should only be used to overlap safe departures. Positive associations can also be formed between the odor and the presentation of food that may be useful for facilitating more relaxed and contented behavior. Perhaps, in the future, inexpensive timers will be available that can be used to turn on the pump periodically for brief and variable periods of time during the day to deliver the conditioned odor and food. Dilute odors such as lavender and chamomile may exert unconditioned mood-enhancing effects when delivered by diffuser.

Graduated Departures and Separation Distress

Many separation problems can be worked out without crate confinement, but usually some room or safe area (e.g., pen) is selected where the dog can be kept when left alone. In some cases, however, the crate may provide a secure place attachment from which to organize separation-related treatment activities. Before staging actual departures, the dog is first exposed to a series of planned-departure rehearsals while confined or crated in a separate room and the owner waiting in another part of the house. The room chosen for this purpose should be the same one used for confinement purposes when the dog is left alone during the day. Usually, a bedroom or kitchen is selected for such purposes, mainly because the dog has probably already formed significant place attachments or other positive associations with those areas. Both places appear to evoke strong and beneficial contextual effects. The bedroom, for example, may elicit relaxation and other effects associated with sleep, while the kitchen may be associated with a number of social and appetitive interests for the dog. The room is provided with a rug or blanket, a towel scented with the owner's odor, and other accoutrements to create a safe, comfortable, and relaxing ambience. Isolating a separation-reactive dog in a remote part of the house (e.g., the basement or garage) or outside on a chain is not only counterproductive, but may be dangerous and should be avoided. During rehearsal departures, the dog is left in the safe room for progressively longer periods, as determined by its tolerance and ability to cope with separation. It is important to keep these programmed separations brief enough to prevent the dog from becoming overly distressed or frustrated. Responding to the dog at such times by releasing it or attempting to calm it should also be carefully avoided. Frustrative persistence can be maintained on a surprisingly lean schedule of reinforcement. On the other hand, allowing the dog to persist in demanding barking or frenetic efforts to escape confinement is also inappropriate.

Barking behavior can often be interrupted with a squeaker followed by a click and treat when the dog defers its attention. Subsequent rewards are delivered in accordance with a DRO schedule such that the reward is produced only if barking does not occur during some brief period (2, 3, 10, 5, 7, 3, 5, 8, 15 seconds, and so forth on a variable basis). The only requirement put on the dog is that it not bark during the no-bark period. Alternatively, the barking behavior can be brought under stimulus control before off-cue barking is extinguished in accordance with instructions discussed in Chapter 5 (see *Barking*). If barking occurs, "Quiet," the vocal signal discriminating the no-bark contingency, is introduced or a firm "Enough" is spoken in a sharp and clipped manner, if a stronger impression is

needed. Again, at brief intervals, the dog is prompted to "Speak" and rewarded. The procedure is repeated many times in order to establish the necessary associative linkages. However, if despite such efforts the dog continues to bark, it may be necessary to employ a disrupter-type event or startle technique to stop the behavior from escalating (see *Guidelines for Successful Crate Training: Step 3* in Chapter 2).

Although many more or less sophisticated procedures can be employed for this purpose (e.g., a remote-activated citronella collar), the most simple and effective tool is a shaker can. The following recommendations assume that the dog has been habituated to the crate or safe room and that the undesirable behavior is likely driven by frustration. The shaker can (see *Miscellaneous Items* in Chapter 1) is introduced by tossing it near the dog while it is barking or attempting to escape confinement. The startling experience will sensitize the dog to the sound of the can, making its rattle an effective disruptive stimulus. Punishment of this sort briefly disrupts and inhibits the barking pattern so that the owner can return and positively reinforce more appropriate behavior. If allowed to bark, many dogs appear to become progressively distressed as the barking continues, but may immediately show signs of relaxation and contentment soon after an effective startle deterrent is applied. The disruptive startle elicited by the shaker can interrupts the cycle of increased arousal and demanding behavior, thereby allowing the owner to reward more cooperative behavior. Some separation-related barking that occurs when the owner is out of sight or outside of the house can be controlled by connecting an inexpensive remote-activated switch to an alarm, radio, or cassette player with a recorded message left on it. The remote switch provides an effective means to disrupt the undesirable behavior without requiring that the owner return to the dog while it is still barking—a potentially highly reinforcing event for a separation-frustrated dog. When the dog stops barking, the owner can return to the dog and reinforce quiet waiting behavior. Ideally, however, programmed separations should progress so gradually that the dog is not unnecessarily challenged or distressed, but if it does become reactive, the shaker can provides an expedient source of inhibitory control. In balance, allowing a dog to bark at such times may be much more stressful than the inhibitory effects produced by the sound of a shaker can or other moderate deterrents, as necessary to establish control (see *Separation-related Problems and Punishment*).

Once the dog is accepting brief periods of separation without signs of distress, safety stimuli such as a radio, light, or odorant can be introduced. For many dogs, the sound of a radio appears to offer some comfort prior to explicit conditioning efforts, perhaps stemming from an association of such stimulation with the presence of the owner. For some dogs, the television is particularly effective, especially in cases where the owner spends more time watching TV than listening to the radio. However, to obtain maximum benefit of safety signals, they should be systematically associated with minimally stressful separations and returns. The radio and light should be turned on just before the owner leaves the room and turned off just before the dog is released from confinement. A tape recording composed of everyday sounds and activities, such as the owner speaking on the telephone, washing dishes, watching television, vacuuming, or whatever else the owner might do while at home, might be made and turned on during departures. The safety tape is played on a continuous loop behind the door or otherwise out of the dog's sight, both during planned departures and when the dog is left alone for longer periods. During planned departures, the dog is given an especially desirable chew toy, such as a hard-rubber toy smeared on the inside with peanut butter or baby food (creamed meats) and stuffed with a biscuit. A nylon bone with several holes drilled into it can be stuffed with hard cheese or other canine delicacies. Such items offer an appetizing diversion for some dogs; however, other dogs seem to prefer the contact comfort of a soft item like a stuffed animal or towel saturated with the owner's smell. In addition to showing a preference for soft toys and cloth items, some evidence suggests that a mirror can provide relief against separation distress (Pettijohn et al., 1977). The

mirror is securely fastened to a wall adjacent to the crate.

A session of planned-departure training involves several trials consisting of graduated and variable durations of separation. A sample session might include the following variable duration (VD) exposures to separation: 5, 45, 10, 60, 20, 30, 45, 5, 120, and 50 seconds (VD, 39 seconds). Care should be taken not to progress too quickly or abruptly from one step to the next, since excessive separation exposure might intensify a dog's distress rather than help to reduce it. Notice that the progression is not a linear one, but varied so that the dog is unable to make any definite predictions about when the owner is likely to return; it only knows that the owner will eventually return after some variable period of separation. From a cognitive-emotional perspective, the aforementioned pattern of exposure results in varying degrees of surprise (the owner returns sooner than expected) and disappointment (the owner returns later than expected), but, ultimately, the owner does return. The combined effect of planned departures is to replace despair and loss at separation with hope, with the dog learning that patient waiting results in the eventual return of the owner. The expectant anticipation of the owner's eventual return appears to compete with adverse separation distress and frustration. For example, it has often been noted that many separation-reactive dogs are not apparently distressed when left in a car. Such dogs appear to have learned that calmly waiting for the owner's return eventually pays off. Apparently, the intermittent schedule of the owner's departures and returns to the car are sufficiently brief, frequent, and variable to facilitate a state conducive to separation security. Such dogs have learned to expect that their owners will eventually return and are comforted during periods of separation by a sense of hopefulness or positive anticipation about their owners' eventual return.

The time between exposure trials (intertrial interval) also appears to be an important variable. During the early stages of training, when very brief and unstressful separation exposures occur under the counterconditioning influence of an attractive or appetitive stimulus, the influence of the intertrial interval may not be significant. However, separation exposures involving durations of a minute or longer may require a more lengthy recovery period between separation-exposure trials. The recommended interval between trials of separation exposure ranges between 1 and 3 minutes, depending on the dog's response.

The success of planned departures is not based solely on the absence of separation distress, but also depends on before-and-after separation behavior. Ideally, the dog should gradually accept separation exposures without showing evidence of worry or other efforts aimed at forestalling separation. During actual departures, the dog should be given 5 to 10 minutes of basic obedience training and confined at least 15 or 20 minutes before the owner leaves, with the owner periodically returning to the confinement area to give the dog a treat. In some cases, massage and the presentation of a conditioned olfactory stimulus can be very beneficial as transitional aids to help reduce excessive arousal before departures and after homecomings (see *Taction and Olfactory Conditioning*). To forestall excessive greeting activity, a dog can be trained for a minute or 2 while remaining in the crate, requiring that it orient and attend briefly before bridging and rewarding the behavior. As the dog becomes more focused and calm, it is released and the training activity is continued outside of the crate for additional 5 to 10 minutes. Appetitive arousal produced by conditioned reinforcers and food appears to help restrain social arousal, perhaps by means of an oxytocin-mediated calming effect occurring in response to food reinforcement and social rewards (see *Origin of Reactive versus Adaptive Coping Styles*).

Counterconditioning Predeparture Cues

As already noted, separation-reactive dogs may show pronounced signs of rising apprehension whenever the owner prepares to leave the house. Such anticipatory arousal is the result of the dog recognizing a predictive relationship between certain of the owner's habits and separation. These predeparture activities (putting on shoes, picking up keys, and similar things) motivationally prime a dog to exhibit various comfort-seeking or separation-

delaying behaviors. In addition to setting the occasion for such behavior, if the behavior happens to be even marginally effective at forestalling the separation event, the underlying motivational arousal present at the time makes it certain that the behavior will undergo marked reinforcement. At such times, any efforts by the owner to calm or to compensate the dog otherwise for the impending separation will likely result in an increase in undesirable preseparation behavior. In addition, this anticipatory arousal to impending separation sets into motion the preliminary conditions for the expression of more intense separation distress or panic when the owner actually leaves the house.

Essentially, predeparture cues are conditioned stimuli that elicit preparatory emotional arousal in anticipation of heightened distress and panic that usually ensue whenever the dog is exposed to separation. Preseparation arousal and activities involve complex operant-respondent interactions. Consequently, the process of changing the associative, behavioral, and motivational implications of predeparture stimuli involves the use of both instrumental shaping and classical counterconditioning techniques. Predeparture cues are counterconditioned in various ways:

- *Engage the dog in some highly attractive activity while simultaneously exposing it to predeparture rituals.* One way to do this to give the dog an appetizing chew item that will occupy it while pretending to get ready to leave.
- *Explicitly pair predeparture cues with antagonistic attractive or appetitive stimuli.* In this case, items such as keys or a briefcase are picked up and immediately followed by giving the dog a food treat. Another situation might be staged where the owner picks up car keys and umbrella only to sit down again, tossing the incredulous dog a treat. Another possibility involves the owner putting on work clothes before feeding the dog. Other possibilities include picking up a briefcase or performing some other predeparture sequence and surprising the dog by taking it for a walk, initiating a brief play session with a favorite toy or ball, or massage.
- *Condition predeparture cues as discriminative stimuli for cooperative behavior.* The owner puts shoes and coat on and then has the dog lie down and stay for several minutes while periodically receiving treats. At other times, a session of basic training could be carried out.
- *Extinguish aversive associations by repeatedly performing predeparture sequences without actually leaving home.* For example, the owner periodically picks up keys only to put them back down again. A variety of predeparture sequences are initiated and concluded without the owner leaving the house. The overall effect is to scramble associations so thoroughly with regard to predeparture activities that the dog is unable to predict when separation is likely to occur. *Note:* Scrambling predeparture cues may help to dissociate them from the actual departure event, but some separation-anxious dogs may become significantly worse as the result of the scrambling procedure. In such dogs, scrambling may raise anxiety levels by decreasing the dog's ability to predict when the owner will leave the house, appearing to cause them to become more vigilant for the event. Many dogs showing separation distress with anxiety or panic appear to do better if predeparture cues are left unscrambled.
- *Shape more appropriate behavior occurring in the presence of evocative predeparture cues.* After putting on work clothes, the owner systematically reinforces behavior such as turning away or laying down.

In general, the goal of these procedures is to alter the dog's expectations about the significance of preseparation events or to reinforce more appropriate preseparation behavior.

Practical Limitations and Compliance Issues

Performing graduated departures and counterconditioning or scrambling predeparture cues appears to be effective, but the precise value of these procedures for the control of SDS is not known. Although most dog behavior therapists seem to agree that graduated departure training

is beneficial, some have criticized the complexity and difficulty of the method for the average dog owner to implement. The success of graduated departure training depends on highly controlled circumstances of exposure and diligent owners willing to commit the necessary time to make the process work. The biggest obstacle is ensuring that the dog is not left alone for too long during the treatment program—a commitment that can last several weeks. Although some dedicated dog owners can find time to carry out planned departures while at home in the evening or on weekends, they must inevitably leave the dog alone. In principle, lengthy exposures to separation should adversely impact the positive gains achieved by desensitization efforts.

Several methods might be considered to address this difficulty. The owner might be fortunate enough to find a neighbor or friend with whom the dog can stay for the first few days or weeks of training. Another method involves hiring a dog walker to carry out graduated departures after the owner leaves for the day. Finally, the owner might borrow a friend's dog (perhaps also left alone during the day), which the resident dog knows and likes, to stay with the distressed dog on a trial basis. Although such an arrangement may sometimes work (Houpt, 1979), it often does not (Voith and Borchelt, 1985) and may be highly stressful for the visiting dog. The arrangement should be discontinued if the distressed dog continues to exhibit a high degree of separation distress. In some cases, the owner might be able to take the dog to work temporarily, but this option does little to improve the dog's behavior when it must be left alone at home. Other options include kenneling or dog day care. Lastly, various medications may be considered as a temporary means to control excessive distress, especially if the dog must be left alone while undergoing desensitization (Voith and Borchelt, 1985).

Quality of Social Attachment and Detachment Training

Attachment and Detachment

The difficulties associated with the graduated departure procedure have prompted the development of techniques designed to alter attachment levels via the implementation of interactive stressors (e.g., ignoring care-seeking behavior, refusing the dog physical contact, removing the dog from the bedroom, and continuous crate confinement). Detachment procedures are premised on the belief that SDS is the result of a dog's poorly regulated attachment behavior. Presumably, as the result of excessive and unregulated social contact, the dog becomes exceedingly and problematically attached to the owner, making separations evocative of disruptive distress and a gradual breakdown of the dog's ability to cope at separation. According to this view, the amount of distress shown by the dog at separation is proportional to the degree of attachment between the dog and the owner.

The significance of attachment levels and proximity seeking in the etiology of adult separation distress has been questioned by various authors [Voith et al., 1997; Goodloe and Borchelt, 1998 (see *Attachment, Proximity Seeking, and Family Size* in Volume 2, Chapter 4)]. In addition, Bradshaw and colleagues (2002) failed to detect any relationship between the amount of owner-dog interaction and the probability of separation-related behavior from month 3 to month 18, further questioning the attachment hypothesis. These reports suggest that it is not a dog's overt attachment or the amount of interaction between the owner and dog that underlies separation-related problems, but rather the way in which the dog copes with being left alone. Most dogs develop strong attachments toward their owners, but only a small percentage of them go on to exhibit clinical separation distress. Many separation-reactive dogs are quite content at separation so long as some human is nearby, even someone with whom the dog has not formed a particularly strong attachment.

The attachment hypothesis appears to confuse effects with causes. Attachment excesses may follow more directly as the result of agitation and distress at separation and a compromised capacity for coping with stress adaptively (see *Origin of Reactive versus Adaptive Coping Styles*), rather than as the result of unregulated affiliative interaction between the dog and owner. The daily agita-

tion and distress at separation followed by relief by the owner's return probably results in the evident contact-seeking behavior exhibited by separation-reactive dogs. In other words, separation-reactive dogs may follow their owners around and seek contact, not because of unregulated affiliation, but rather because of a history of unregulated separation distress and agitation. According to this view, excessive attachment is not the cause of separation distress; on the contrary, excessive attachment is more likely the result of heightened agitation and distress at separation. Consequently, the arbitrary reduction of proximity seeking and attachment behavior between the owner and dog may not serve to alter significantly the causes of separation reactivity and dysregulation, but may instead inadvertently increase social contact needs and problematic attachment behavior. Consequently, detachment procedures and interactive stressors aimed at reducing contact and attachment behavior may inadvertently increase attachment levels via the emotional agitation, frustration, and insecurity produced by the detachment procedure itself, many components of which are highly punitive and restrictive with regard to a dog's social initiatives. The use of interactive stressors to modify attachment behavior is contrary to the enhancement of social competency, confidence building (intrinsic counterconditioning by relaxation), and reward-based stress modulation via enhanced comfort and safety-security. Ultimately, the best way to reduce excessive and insecure attachment behavior is not by arbitrarily implementing interactive stressors designed to unilaterally limit contact between the dog and the owner, but rather by reducing the amount of agitation and distress the dog experiences at separation, while at the same time training it to respond more adaptively to stressful situations, and, most importantly, improving the quality of the social bond between the owner and dog—not weakening or dismantling it.

Despite some disagreement on the matter of how attachment levels influence the development of SDS, evidence suggests that close and exclusive attachments probably do play a significant role in the etiology of some separation-related problems (see *Attachment, Proximity Seeking, and Family Size* in Volume 2, Chapter 4). Dogs exhibiting a strong attachment toward a particular family member appear to be at an increased risk of developing separation problems (McBride et al., 1995). Topál and colleagues (1998) found that dogs living in large family groups exhibit less separation distress when tested than dogs coming from families with fewer members. Data from a clinical population indicated that most separation-reactive dogs live in small family groups containing two adults and no children (Podberscek et al., 1999). Flannigan and Dodman (2001) have confirmed that family size is a significant risk factor associated with separation-related behavior problems, finding that dogs kept by a single owner are 2.5 times more likely to exhibit separation problems—a risk factor previously missed (McBride et al., 1995). Surprisingly, the presence of another dog in the household does not appear to reduce the risk of separation problems (Flannigan and Dodman, 2001). This finding seems odd since dogs generally appear to cope better with separation when living with another dog or cat. As already discussed, the presence of another dog does not ensure that canine company will comfort an already separation-distressed dog, but one would expect some preventive benefit as the result of the formation of bonds with other animals in the household. Nonetheless, consistent with the findings of Flannigan and Dodman, McBride and colleagues (1995) also found that the incidence of separation-related problems among dogs adopted from an animal shelter was not significantly related to the presence of another dog in the new home. Dogs placed in homes with at least one cat, though, were less likely to exhibit separation-related problems—a curious finding needing additional study.

In a sense, many treatment protocols seem to have misidentified the social symptoms of SDS as the causes of the problem. Although modifying and managing symptoms may exert some beneficial influence, whenever possible treatment efforts should focus on primary causes—not effects and symptoms. Unless agitation and distress at separation are

reduced, heightened levels of attachment and contact needs will probably continue unabated, perhaps worsening as the result of implementing intrusive detachment procedures (Table 4.3).

Detachment training may be transitionally useful in some cases involving extreme attachment disorganization, but the necessity of interactive stressors to reduce separation-related problems has not been scientifically established. Further, there is no significant evidence supporting the belief that spoiling activities or permissiveness with respect to attachment behaviors (e.g., sleeping on the bed) are causally related to separation-related problems (see Flannigan and Dodman, 2001; and Voith et al., 1992). Also, the common belief that excessive fussing during departures and greetings is causally related to separation problems is not supported by the current data (McBride et al., 1995). For highly attached dogs, the introduction of detachment training may introduce additional conflict and confusion, resulting in further disruption and distress at separation, perhaps making matters worse and the problem more difficult to resolve in some cases. In general, the key is not to detach the dog from the owner arbitrarily and unilaterally, and possibly further undermine its social confidence and make the relationship more unstable and the dog more reactive, but to enhance the bond between the owner and dog through training. The dog's need for contact and proximity can be directed into constructive training activities that support interactive harmony, enhanced confidence, and social independence. Rather than emphasizing detachment training as a way of life, behavioral efforts are much better dedicated to independence training, whereby the dog learns to cope more competently and confidently with separation and aloneness (see *Cynopraxis and the Human-Dog Bond* in Volume 1, Chapter 10). Finally, detachment procedures are often highly intrusive, perhaps being more aversive to some owners to carry out than coping with a dog's separation problems. Consequently, even in the event that detachment procedures work, it is unlikely that the owner will want to indefinitely maintain the interaction needed to support the detachment effect.

Dynamics of Bonding: Nurturance, Dominance, and Leadership

Since the quality of attachment and bonding (mutual ties) between the owner and dog appears to play a prominent role in the development of SDS, it makes sense to build on the dog's affection and attachment, taking what one finds and guiding it into a more healthy and mutually satisfying form. In other words, treatment should focus on repairing disorganized aspects of attachment behavior, rather than suppress and impede attachment behavior in general. The relationship between humans and dogs is formed under the influence of three fundamental and complementary bonds that dynamically interact with one another: (1) nurturer-dependent bond, (2) dominant-subordinate bond, and (3) leader-follower bond. Note that each bond consists of two modes of

TABLE. 4.3. Summary of common detachment procedures

The owner must ignore all of the dog's social solicitations for contact.
Proximity-seeking behavior is discouraged by command or confinement.
The dog is separated for progressively longer periods while the owner is at home.
The dog is forbidden from sitting on the owner's lap or to share furniture.
The dog is not permitted to sleep or be in the bedroom at night.
The dog must earn all appetitive and social rewards.
The dog's greeting behavior is ignored or discouraged.

mutual reciprocation by which the owner and the dog relate to each other. A healthy human-dog relationship is based on a balance of nurturance and dependency, dominance and submission, and leadership and cooperation. Inadequacies or excesses in any of these three basic binary dimensions of social interaction may cause disharmony and disturbance in the social relations between people and dogs.

A common source of confusion is distinguishing between dominance and leadership. Many authors seem to treat dominance and leadership as synonyms meaning approximately the same thing. Dominance-related interaction involving covert, subtle, or overt threats of force or the use of actual force of varying degrees (e.g., holding the dog back from some activity or shoving it off as it jumps up) and submissive acknowledgment by the dog serve to set social limits and define what a dog cannot do. The effect of submission is primarily inhibitory, causing a dog to avoid certain behaviors, at least while in the owner's presence, but without specifying what the dog ought to do instead. Dominant-subordinate interaction involves overt contests or threat-appeasement displays, activities that appear to enhance affectionate tolerance (dominant role) and affectionate attraction (subordinate role). Affection arising from dominant-subordinate interaction causes the subordinate paradoxically to seek closer proximity with the dominator (see *Social Distance and Polarity* in Volume 2, Chapter 8). Attention seeking and proximity seeking reflect a highly submissive and inhibited orientation in which the dependent subordinate is looking for leadership and guidance—it literally needs to be shown what to do. The direction of social interaction between the dominator and the subordinate is highly directional or polarized. Social polarity is manifested in care-seeking activities, such as attention-seeking, affection-seeking, and proximity-seeking behavior. The establishment of dominant-subordinate relations prepares the subordinate to become a dependent and cooperative follower if adequate leadership is provided. However, a highly submissive dog, in the absence of leadership, may be vulnerable to develop insecure attachment, especially if the dominator is primarily a source of nurturance and fails to *own* the responsibility of leadership. Social dominance without leadership is a formula for behavioral and emotional imbalance and insecurity, potentially giving rise to extremes of abusive domination, on the one hand, and careless indulgence, on the other.

Whereas transactions involving the exchange of threat and appeasement displays establish that certain behaviors are forbidden, leadership helps to guide the dependent subordinate into activities that are acceptable and lead to various sources of appetitive and social gratification. Leadership is associated with the initiation and coordination of cooperative activities that result in benefit for both the leader and the follower. Whereas submission exerts an inhibitory influence, following provides an excitatory influence on behavior. The result of dominance is submission, affection, and dependency, whereas leadership provides the basis for social cooperation and interactive harmony. With respect to the human-dog bond, it would seem that excessive proximity seeking and affection seeking are not symptoms of attachment excess, but reflect a submissive and dependent search for leadership. The relation between dominance, leadership, and nurturance is reflected in the moment-to-moment ebb and flow of social interaction, defining what is not done, what is done, and the sorts of appetitive and affectionate gratifications that accrue as the result of cooperative and harmonious interaction. The process of obedience training incorporates all three dimensions of the bonding triune in a balanced relationship. Basic training defines what a dog may not do (e.g., jump up, bite on hands and clothes, and pull on the leash), shows the dog what it may do (jump up on signal, play tug and retrieve, controlled-leash walking, sit, stay, come, and so forth), and provides contingent nurturance (e.g., affectionate petting and food) based on cooperative behavior.

Owners of separation-distressed dogs need some specific things to do, but more importantly they need principles (more than rules and recipes) to guide their daily interactions with the dog. Having a separation-distressed dog perform repetitive sit-stay exercises and other unilateral and arbitrary detachment initiatives (rejection of attention and contact, blocking of proximity seeking, and cessation of noncontingent affection and rewards) may fully miss the point unless the owner is led to a better appreciation of the dynamic interplay between dominance, leadership, and nurturance in the process of balanced and healthy bonding. An important step in this direction is to teach owners to appreciate their dog's behavior as form of communication needing thoughtful interpretation and understanding.

BASIC TRAINING AND SEPARATION DISTRESS

One of the best ways to restore appropriate limits and balance to the human-dog relationship is basic training. Not surprisingly, obedience training has been correlated with a reduced incidence of separation-related complaints (Goodloe and Borchelt, 1998; Jagoe and Serpell, 1996; Flannigan and Dodman, 2001), possibly as the result of organized attachment behavior and the enhanced confidence promoted by obedience training. Clark and Boyer (1993), also noting that obedience training appears to have a pronounced effect on separation-related behavior problems, speculate that obedience-trained dogs appear to be more secure in their attachments—a security that may be the result of enhanced owner-dog communication and interaction. Dogs without a viable channel of communication may be unable to relate to the owner as an independent affiliative partner, a failing that may predispose it to develop a persistent and regressive reliance on direct contact and vulnerability at separation:

> Ainsworth (1972) found that separation distress becomes less significant as children become better able to sustain attachment in abstentia and that close proximity and contact may, to some extent, be supplanted by communication and interaction across a distance. Thus obedience training may be the communication tool for the owner to provide security in the relationship and improve the human-canine relationship. Obedience training may facilitate feelings of security for dogs, because training communicates proper behavior by reinforcing appropriate behavior and punishing inappropriate behaviour. (157)

In addition to preventing or reversing problematic dependency and enhancing an owner's leadership, basic training improves a dog's attentional and impulse-control abilities—two vital cortical executive functions necessary for effective adaptation under stress. Most importantly, though, for purposes of separation-distress problems, no other activity improves a dog's confidence and sense of security better than basic training. Training activity should be integrated into the everyday interaction between the owner and dog. A "no pay, no play" philosophy may be instituted in which the dog learns that attention and affection are earned most effectively by cooperative behavior. The heightened social contact needs associated with homecomings should be harnessed to the furtherance of training objectives (see *Establishing Operations* in Chapter 1). At such times, dogs are acutely sensitive to petting and praise as rewards. Instead of ignoring or simply giving a dog the attention and contact stimulation that it craves, a cycle of basic training exercises can be performed in exchange for social and appetitive rewards. Because all dogs, like people, are different and require training designed to meet their specific needs, basic training is best carried out under the supervision of an applied dog behaviorist or a skilled trainer familiar with the needs of the separation-reactive dog.

Although basic training may not directly modify separation distress or frustration, it offers a useful and proven means for clarifying social boundaries and establishing general control that may be extremely beneficial. Takeuchi and colleagues (2001) found that owners with separation-anxious dogs tended to indulge them and used verbal discipline rather than physical means to control undesirable behavior. Separation-reactive dogs are often very skilled at getting their way by emotionally or physically manipulating their owner. These tactics and schemes may entrap

a naive owner in a subtle web of obligatory expectations and emotional pressures to concede to the dog's demands. Having maneuvered into a position of emotional leverage over the owner, the dog may find it extremely difficult to cope with situations where its control is compromised or forfeited, as occurs at separation. A dog that is accustomed to getting and controlling the owner's attention and proximity on demand may be more prone to become frustrated when the behavior fails to work, as occurs when the owner must leave the dog alone. Under the influence of frustration and secondary distress at separation, separation-reactive dogs may exhibit and intensify protest behaviors that have succeeded in past to get the owner's attention (e.g., barking, scratching on doors, or grabbing personal belongings).

From an early age onward, dogs may learn that certain undesirable behaviors are a sure way to get attention, albeit not always the most desirable attention. For some dogs, the preponderance of the daily interaction and attention received during puppyhood may have been primarily obtained by way of disciplinary interaction directed at suppressing such problematic attention-seeking behavior. Many of these behaviors are similar to the array of protest behaviors occurring at separation. As previously discussed, punitive interaction may potentiate dependency and attachment behavior in dogs (see *Early Trauma and the Development of Behavior Problems* in Volume 2, Chapter 2). Faced with separation frustration and distress, dogs may resort to those same behaviors that have worked in the past to protest and get the owner's attention. Retroactive punishment (punishment directed against past deeds), which is common in the case of separation-reactive dogs (see *Separation Distress and Retroactive Punishment* in Volume 2, Chapter 4), is highly undesirable and problematic, appearing to increase the dog's dependency and vulnerability to emotional distress at separation, potentially setting into action a vicious cycle of punishment and increased separation-related reactivity. Since retroactive punishment is relatively unpredictable and uncontrollable, it may impair the dog's ability to trust the owner as a source of safety and consistency, leading in extreme cases to significant cognitive and emotional disorganization.

Separation-related Problems and Punishment

Separation distress is potentiated by a number of coactive motivational and emotional influences, especially frustration, boredom, fear, and panic. The role of these various contributing motivational influences in the expression of separation-related behavior should be carefully assessed before considering the use of punishment. Obviously, punishment would be an entirely inappropriate option in the case of highly unstable and reactive dogs. Also, it must be emphasized that punishment may worsen some separation-related problems, especially those presenting under the influence of panic, making the use of punishment risky and requiring careful monitoring. As mentioned previously, inappropriate or excessive punitive treatment may paradoxically enhance attachment behavior and risk increasing separation-related problems. Further, without appropriate support conditioning aimed at reducing the dog's aversive emotional response to separation, a possibility exists that the dog, unable to find relief in its preferred modality, may redirect its distress-reducing impulses into other, perhaps even more undesirable and difficult-to-control, activities. Despite significant concerns and reservations, some forms of separation-related behavior, especially barking problems and destructiveness resulting from protest at separation, appear to be highly responsive to certain punitive procedures. Although the method is not popular with some and despite some authoritative opinions to the contrary, separation-related barking is often highly responsive to aversive treatment procedures involving the use of bark-activated collar devices. Barking problems may require timely intervention and modification, with the owner facing imminent eviction or costly nuisance citations. Many owners who have independently resorted to the use of bark-activated collars to treat such behaviors have reported a high degree of success. The use of bark-activated collars to suppress barking is risky and can result in disaster in the case of

panic-related separation problems, which appear to escalate dramatically under the excitatory influence of fear (see *ES and Excessive Barking* in Chapter 9). Although crating or penning a dog can control destructive habits temporarily, eventually the dog is released from confinement and exposed to at least part of the house. Giving such a dog increased freedom and comfort may result in undesirable exploration and destructive behavior. Various techniques involving repellents, booby traps, and electronic devices are used selectively to prevent or suppress such behavior in the owner's absence. The details of these various procedures are described in Chapter 2 (see *Miscellaneous Devices and Techniques for Deterring Destructive Behavior*).

MASSAGE, PLAY, AND EXERCISE

Taction and Olfactory Conditioning

Massage and relaxation training have many applications in the management of dog behavior, especially in situations involving aversive emotional arousal such as separation distress (Tuber, 1986). The first systematic effort to quantify the calming effect of human taction on dogs was performed by Gantt and colleagues (1966), who observed that many dogs in distress are calmed by social contact, exhibiting a significant decrease in both heart and respiratory rates while being petted. The authors referred to this phenomenon as the *effect of person* (see *The Effect of Person* in Volume 1, Chapter 10).

In conjunction with tactile stimulation, olfactory stimulation appears to play a significant role in the formation of social attachments and bonds (see *Biological and Social Functions of Smell* in Volume 1, Chapter 4). Among rat pups, odors appear to facilitate huddling behavior, with olfactory incentives developmentally supplanting thermal and tactile ones in the regulation of such behavior (Rosenblatt, 1983). Unfortunately, the full emotional significance and value of the sense of smell for dogs remain elusive and conjectural. There is little doubt that olfaction plays an important role in emotional learning and attachment (see *Social Comfort Seeking and Distress* in Volume 2, Chapter 4). The social significance of olfactory information is highly durable in dogs. They exhibit evidence of recognizing the scent of the mother and the breeder after years of separation, social memories that may persist throughout a dog's life cycle (Hepper, 1994; Appel et al., 1999). By way of limbic system projections, olfactory information may exert significant conditioned and unconditioned effects involving various neuropeptide systems (e.g., opioid, oxytocin, and AVP) believed to play a role in the expression of social emotions and memories. As the result of direct connections with the amygdala, strong links between olfaction and social aversion may be established. The amygdala plays a central role in fear learning and exercises a powerful modulatory influence over the expression of fear via connections with hypothalamic nuclei dedicated to elaboration of fear, startle, and stress responses (see *Limbic System* in Volume 1, Chapter 3). Olfactory stimulation is easily and rapidly conditioned to produce emotional alarm. Through interconnections with the amygdala (emotional memory) and hippocampus (contextual memory), olfactory learning may exert a significant conditioned influence over the release of CRF and the cascade of events associated with biological stress. In addition to these subcortical influences, olfaction reaches cortical representation through interconnections among the amygdala, the hippocampus, the thalamus, and the prefrontal cortex, where the information is further processed, accessed by the working memory, and coordinated with goal-directed activities. The role of olfaction at the level of cognition has received very little attention in dogs, but in rodents there is growing evidence to suggest that they may "think" with their noses (Slotnick, 1994; Slotnick et al., 2000).

The canine olfactory system provides a powerful means to influence separation distress through conditioned associations with safety (relief), physical and emotional relaxation, appetitive stimuli, and play activities. Olfactory stimuli associated with predeparture activities appears to exert significant preparatory influences on a dog's emotional response to separation. Odors (e.g., the smell of coffee or the owner's cologne or deodorant) repeatedly present at departure may

become potent conditioned olfactory stressors, perhaps contributing significantly to a dog's reaction at separation. Like other conditioned predeparture stimuli, olfactory stressors need to be identified and counterconditioned whenever possible. On the other hand, olfactory stimuli associated with the owner homecomings may acquire potent conditioned relief and safety associations that can be used to counter agitation and distress associated with separations. The apparent efficacy of the owner's scent on towels and so forth to quell separation distress may be derived largely from olfactory conditioning that occurs during greetings. Putting on a scent used during safety conditioning and PFR training (e.g., orange or lemon-orange mix) just before entering the house to greet the dog or puppy after a long separation may help to intensify the effect of the odor as a conditioned source of security for the dog.

Massage is a useful way to calm a separation-reactive dog while performing graduated departures. Dogs that become overly aroused at departures and homecomings are often highly responsive to 3 to 5 minutes of PFR training just before the owner leaves and again after the owner returns home. The method used follows the guidelines and procedures described in Appendix C. Although not all dogs are equally responsive to massage, most appear to benefit from the experience. For many dogs, massage produces a pronounced and easily replicated relaxation response. In addition to the direct benefits of massage-induced relaxation, the focused and unambiguous contact comfort produced by massage may exert ancillary therapeutic benefit by modulating the production and release of neuropeptides (e.g., oxytocin, endogenous opioids, and CRF) involved in the mediation of contact comfort and separation distress. To capture the benefits of massage and optimize the ability to generalize the benefits across contexts, an olfactory stimulus is paired with massage-induced relaxation. Once conditioned, the odor can be used during graduated departures and predepartures as an OSS. Performing massage in the presence of other safety signals (e.g., music, radio, and light) can help to support and augment the effect of such signals. To help transfer and generalize the olfactory association, the owner can place a drop or two of the fragrant oil on the hands while carrying out planned departures.

Various odor diffusers are available that can be used to present the OSS over time. A diffuser is made by drilling two small holes into the cap of a small bottle and inserting rubber tubing into the holes, with one of the tubes (the outlet) extending to the vicinity of the crate and the other (the inlet) attached to the aquarium pump. The tubes should form an airtight seal with the lid. A dilute fragrant odor can be put on several cotton balls that are placed on top of the inlet tube or the odor can be diluted in water and released by a bubbling action. The outlet tube should be situated an inch or so below the lid so that it does not touch the water. A ceramic ring that is heated by a light bulb can also be used to diffuse fragrant oils. The dilute essential oil is simply dripped onto the ceramic ring before leaving the house. When graduated departure activities are performed, the light is switched on, thereby combining the effects of two safety signals in one action. Alternatively, a plug-in room freshener can be modified so that the conditioned OSS is released instead of the packaged odorant coming with the unit.

Play and Exercise

Play and exercise appear to exert a positive influence on the treatment of separation-related problems. Play offers a ready means to normalize the social interaction between the owner and dog, reduce stress, and enhance affiliation, confidence, cooperation, and emotional flexibility, thereby helping to harmonize human-dog interaction. Engaging the dog in object-oriented play (e.g., tug and fetch) also provides a source of highly enjoyable aerobic exercise. The provision of supplemental exercise may be particularly important in the case of active, working, or sporting-type dogs with separation-related problems. Exercise appears to exert a variety of neurobiological effects, including a robust influence on serotonergic activity (see *Exercise and the Neuroeconomy of Stress* in Volume 1, Chapter 3).

Separation-reactive dogs should be exercised daily. An excellent exercise plan incorporates a combination of long walks and playing fetch with a ball or soft disk. Walks as brief as 20 minutes or so can be very beneficial, but some dogs may require much more exercise to produce a benefit (Radosevich et al., 1989). The crucial consideration with regard to exercise is that it be provided on a consistent and daily basis. Exercise scheduled erratically or on impulse may result in additional problems. For example, taking the dog for a 5-mile walk 1 day, skipping 2 or 3 days, and then jogging the dog for a week, followed by a week without any exercise—this sort of pattern may be more stressful and tension producing than relaxing for the dog. The best rule of thumb is to provide the dog with adequate exercise, play, and training on a consistent basis every day.

Compulsive and Hyperactive Excesses

PART 1: COMPULSIVE BEHAVIOR DISORDERS

Dogs exhibit a variety of compulsive behavior problems. Compulsions typically involve species-typical behavior patterns that are performed repetitively, excessively, and out of normal context. Many common compulsive habits appear to involve disturbances of the seeking system and the exaggeration of normal canine behavior, occurring under the influence of frustration, anxiety, and conflict, especially social conflict. Frustration of the seeking system caused by environmental constraints that thwart the animal's ability to explore, hunt, and obtain normal daily gratification of species-typical appetitive interests may prompt a variety of compensatory compulsive or adjunctive behavior excesses [e.g., schedule-induced licking (see *Displacement Activities and Compulsion* in Volume 2, Chapter 5)]. Self-directed stimulation and injurious behaviors (e.g., self-licking, chewing, scratching and sucking), self-directed motor stereotypies (e.g., tail chasing, whirling, and air snapping), appetitive compulsions (e.g., pica, excessive eating and drinking, destructive chewing, and floor licking), social excesses (attention seeking, barking, licking, and pawing), and locomotor excesses (pacing, jumping in place, and ground or carpet digging) can all be traced to origins in the seeking system. Behaviors belonging to the sexual system can be liberated to become compulsive excesses (e.g., mounting and thrusting on people or inanimate objects). Like tail chasing, mounting and thrusting behavior resists interruption and may in some cases evoke an aggressive response when dogs are restrained or interrupted while engaging in

the behavior. Such behavior may be directed against family members or guests despite intensive inhibitory training and castration. While not customarily described as a compulsion, such behavior presents with many characteristics consistent with a compulsive etiology. The displacement behavior is prevalent during social transitions, especially during greetings and departures, or at other times of increased excitement.

Dogs most prone to develop compulsive behavior problems are frequently high strung and impulsive, temperament dimensions that are exacerbated by adverse environmental conditions. Highly motivated and high-strung dogs that are intolerant of conflict and frustration seem to be particularly at risk for developing compulsive habits. Many dogs appear to exhibit compulsive behaviors at moments of high excitement, suggesting that in some cases compulsions may serve an energy-releasing function. Diagnostically, there is significant overlap between compulsive and impulsive behavior. Differentiating between the two is particularly difficult in the case of repetitive excessive behaviors exhibited by high-strung and excitable dogs. A similar diagnostic difficulty exists in the case of hyperactive versus hyperkinetic dogs (see *Hyperactivity versus Hyperkinesis* in Volume 2, Chapter 5). In general, compulsive behaviors are more exaggerated and resistant to behavior-control efforts than impulsive ones, but even here significant variation exists.

A number of phylogenetically significant behavior systems have been implicated in the development of compulsive stereotypies and rituals, including agonistic, territorial, predatory, grooming, locomotor, and social communication systems. Additionally, separation-related excesses often possess a compulsive character (e.g., repetitive and stereotypic vocal, oral, and motor activities), suggesting that the separation-distress syndrome may involve a similar etiology and functional disturbance (see *Compulsion* in Volume 2, Chapter 4). O'Farrell (1995) has reported evidence suggesting that some compulsive excesses may be linked to owner emotional attachment levels and anthropomorphic attitudes. Licking excesses frequently present in close association with separation-related distress and excessive confinement (Goldberger and Rapoport, 1991). Instrumental modules and modal activities performing agonistic or territorial functions may be compulsively activated under the influence of adverse social or environmental conditions. Tail-chasing behaviors may involve some degree of self-directed aggression (see *Vacuum Behavior* in Volume 2, Chapter 5), with such dogs frequently barking, growling, and snapping at their tails. Interrupting tail-chasing episodes or even standing nearby while one is ongoing may evoke redirected aggressive threats or attacks by the dog, further supporting the notion that an aggressive motivation may underlie the tail-chasing behavior. Among monkeys exposed to prolonged isolation, self-directed biting and head slapping are frequently observed. Jones and Barraclough (1978) have suggested that these compulsive and self-injurious behaviors may involve an aggressive motivation turned against the animal's body. Rapoport (1989) has observed that the checking rituals common to human patients with obsessive-compulsive disorder (OCD) may involve territorial subroutines dedicated to the maintenance of territorial boundaries and order. Recent studies appear to support the notion that territoriality may underlie human checking compulsions. Joiner and Sachs-Ericsson (2001) have detected a significant correlation between high territoriality scores and the severity of obsessive-compulsive symptoms. The excessive scent marking exhibited by some male dogs may reflect a compulsive exaggeration of a territorial module dedicated to checking and marking over urine deposits left behind by other male and female dogs. In some cases, sniffing and marking rituals may become so engrossing that other behaviors are largely displaced by its performance. Under adverse conditions, highly territorial dogs may develop a variety of compulsive excesses associated with the expression of exaggerated or maladaptive territorial subroutines (e.g., excessive barking and environmental vigilance).

Unable to engage in preferred activities, frustrated dogs may cope with the situation by compulsively engaging in alternative behaviors. In addition to conflict and frustration, stress and boredom appear to play a role

in the etiology of compulsive behavior (see *Conflict and Coactive Factors* in Volume 2, Chapter 5). Boredom as the result of insufficient stimulation may be less problematic than boredom resulting from the frustration of exploratory behavior and the reward derived from such activity (see *Separation Distress and Coactive Influences* in Volume 2, Chapter 4). In the case of highly active and unstable extraverts (choleric type), thwarting their ability to explore the environment freely may be intensely aversive. Among such dogs, repetitive compulsive actions may represent a diversion and a significant source of comfort and relief. Boredom in the case of more retiring and introverted types may be less problematic, although unstable introverts (melancholic types) that show anxiety and depressive symptoms at separation may be particularly prone to develop compulsive behaviors aimed at obtaining comfort via lingual stimulation. Dogs expressing relatively balanced and stable temperaments (sanguine and phlegmatic types) appear to be much less at risk for developing compulsive habits under ordinary conditions. These observations are consistent with the supposition that temperament plays a significant predisposing role in the etiology of compulsive behavior disorders (CBDs) in animals (Dallaire, 1993). Temperament also appears to play a prominent role in the development of OCD in humans. Human subjects diagnosed with OCD frequently exhibit comorbid anxiety, depression, and biogenetic temperament dimensions conducive to compulsive disorder, including strong harm-avoidance tendencies, reduced novelty seeking, and impairments in goal-directed activity. The variable presence or absence of these contributory influences significantly affects the severity of symptoms and the patient's response to pharmacological therapy (Lyoo et al., 2001).

Many canine compulsive behaviors appear to develop in close association with increased aversive arousal (e.g., anxiety and frustration) and concomitant physiological changes associated conflict-dense situations and stress. Disruptive behavioral changes are commonly associated with a lack or loss of prediction and control over the social or physical environment. The emotional corollaries of environmental unpredictability and uncontrollability are increased anxiety and frustration. In cases where the environment is disordered, adaptive efforts are stymied by varying levels of conflict-related stress, generalized anxiety, and global behavioral disturbances. The average dog is exposed to a number of intrinsic and inescapable sources of stress stemming from a loss of control over vital interests, including reproductive prerogatives, expression of species-typical activities, free movement, private-space needs, conspecific interaction and company, and other stressors naturally accruing as the result of interspecific interaction and associated prohibitions. Compulsions are often expressed in the form of drive-related behavior (see *Emotional Command Systems and Drive Theory* in Chapter 6). Both compulsive behavior and drive-related behavior are resistant to extinction. Drive activity occurs when a critical arousal threshold is reached in the presence of an appropriate object or target. Similarly, under adverse motivational conditions involving frustration or conflict, disruptive compulsive modules and routines may be launched as critical arousal and frustration levels are exceeded. In addition to drive-related intrinsic reinforcement and gratification, compulsive behavior may be maintained by negative reinforcement insofar as the resulting behavior serves to reduce aversive arousal.

Neurobiology and Compulsive Behavior Disorders

Efforts to localize the brain areas responsible for the expression of compulsive behavior have generally focused on the basal ganglia (Wise and Rapoport, 1989) (see *Neurobiology of Compulsive Behavior and Stereotypies* in Volume 1, Chapter 3). The basal ganglia, also referred to as the striatal complex, consists of several integrated structures, including the caudate nucleus, globus pallidus, nucleus accumbens, ventral tegmental area, and the substantia nigra (Panksepp, 1998). According to the basal ganglia hypothesis, species-typical behaviors stored within the striatal complex as innate motor programs are inappropriately activated under the influence of stressful conflict or frustration. CBDs may ensue when the gating function controlling sensory inputs

impinging on the basal ganglia is disrupted. Among humans exhibiting OCDs, positron-emission tomography indicates that the caudate nucleus of patients exhibiting OCDs is more active than in controls not diagnosed with the disorder (Baxter et al., 1987). Under the influence of biological stress, a cascade of neurobiological changes occurs, including the release of adrenocorticotropic hormone (ACTH) and ß-endorphins by the pituitary. ACTH is a potent elicitor of self-grooming activity in rats when it is injected intracranially. ACTH-elicited grooming behavior can be decreased by opioid antagonists (e.g., naloxone or naltrexone) or increased by administering low doses of morphine (Swedo, 1989). Increased opioid release in response to stress has been demonstrated to sensitize dopamine (DA) receptors to apomorphine-induced stereotypies in mice (Cabib et al., 1984)—an agonist effect that is reversed by the administration of naloxone. Opioid receptors are distributed in close association with dopaminergic and serotonergic circuits believed to mediate the expression of compulsive stereotypies. The interaction between these neurochemical systems remains to be fully elucidated, but it is likely that opioids exert a facilitatory influence over DA activity, at least in some substructures of the striatal complex (e.g., the ventral tegmental area), whereas serotonin (5-hydroxytryptamine or 5-HT) appears to perform an inhibitory function. According to this hypothesis, in combination, opioids and 5-HT serve to functionally modulate striatal DA activity; however, things are far more complicated than the foregoing simple relation would suggest. For example, the interaction between opioid and DA systems in the basal ganglia is complementary, with endorphins producing both excitatory and inhibitory effects, depending on the substructure involved (Panksepp, 1998). Nonetheless, chronic exposure to opiates and ß-endorphins has been shown to sensitize the dopaminergic system, as evidenced by increased stereotypic activity in response to DA agonists following treatment with opiates (Cabib et al., 1984). Interestingly, the efficacy of selective serotonin (5-HT)-reuptake inhibitors (SSRIs) to control compulsive stereotypies may be, in part, due to secondary modulatory effects that they have over opioid activity. Rats exposed to chronic treatment with clomipramine exhibit significant changes in opioid function. Clomipramine has been shown to reduce central opioid levels (met-enkephalin), downregulate opioid receptor sites (mu and kappa), and reduce morphine-induced analgesia (see McDougle et al., 1999).

Opioids via their interaction with DA reward circuits in the ventral tegmental area (VTA) may mediate reward signals that serve to support repetitive stereotypies in the absence of external sources of reinforcement. Many compulsive behaviors belong to the seeking system and presumably operate under the stimulatory influence of DA, especially involving the D2 receptor subtype. DA mediates a variety of neuromodulatory functions, including a central role in making reward pleasurable. Although the relationship between increased DA activity and compulsive behavior is not without ambiguity (Goodman et al., 1992), significant evidence does suggest that DA dysregulation may play a functional role in etiology of some CBDs. Psychostimulants (amphetamines) and a variety of DA agonists injected into the ventrolateral striatum have been shown to induce oral stereotypies (biting, gnawing, and paw nibbling) in rats, an effect that is attenuated by inactivating areas of the substantia nigra (Canales et al., 2000). Amphetamines have also been shown to induce self-directed biting, head tossing, and increased vocalization in horses (Shuster and Dodman, 1998). Similar induction effects have been known to occur in domestic animals (sheep, cattle, and horses) in response to injections of the DA agonist apomorphine for many years (see Fraser, 1985). In bank voles, dose-dependent licking can be induced by apomorphine, but not jumping stereotypies (Vandebroek and Ödberg, 1997), suggesting that stress-related jumping may occur independently of the DA system or depend on a DA receptor subtype not affected apomorphine. The D_2 agonist quinpirole can induce repetitive checking behavior in rats—a behavioral compulsion that has been recently proposed as an ana-

logue of human OCD (Szechtman et al., 2001). Just as some repetitive stereotypies can be pharmacologically induced by increasing DA activity in the striatum, agents blocking or inhibiting DA activity can reduce the expression of such behavior. The differential effects of DA agonists and antagonists depend on the DA receptor subtypes that they specifically target. For example, whereas the D_2 antagonist haloperidol exerts an inhibitory effect over repetitive jumping stereotypies in bank voles (Kennes et al., 1988), clozapine, a D_4 antagonist, does not reduce captivity-induced vole stereotypies (Schoenecker and Heller, 2001). Treatment with haloperidol may result in DA receptor hypersensitivity when the DA antagonist is removed, an enhanced sensitivity that is expressed by increased stereotypic activity in response to DA agonists (e.g., apomorphine)—a modulatory effect that may be mediated by DA presynaptic autoreceptors (Martres et al., 1977).

Stress-induced dysregulation of the 5-HT system is regarded by many authorities as playing a prominent role in the etiology of CBDs. The stress-related activation of the HPA system is initiated by corticotropin-releasing factor (CRF). In addition to precipitating a cascade of peripheral hormonal changes, CRF exerts a pronounced influence on a variety of brain areas, including the inhibition of 5-HT-producing cells localized in the dorsal raphe bodies (Kirby et al., 2000). Price and colleagues (1998) found that intracranial injections of CRF produced a biphasic (inhibitory-excitatory) effect on 5-HT release. Although relatively high doses of CRF appear to increase 5-HT release, the predominant effect of CRF on the dorsal raphe bodies appears to be inhibitory, resulting in decreased 5-HT release in the striatum. In addition, Price and coworkers found that high doses of CRF produced compulsion-like behavioral changes, including intense grooming, burying, and head-shaking activities, behavioral effects that may be mediated via CRF fibers innervating the substantia nigra—the source of DA entering the striatal complex. Acute and chronic stress-related release of CRF appears to exert a significant dysregulatory effect over serotonergic and dopaminergic systems, changes that may render dogs vulnerable to compulsive disorders and other problems associated with impulse-control deficits.

Chronic overproduction of adrenal glucocorticoids may also have a pronounced effect on serotonergic activity. Smythe and colleagues (1994) have reported that brief maternal separation of infant rats (15 minutes per day) during the first 2 weeks of life has a pronounced effect on 5-HT turnover in the frontal cortex and hippocampus, an effect that appears to shadow the proliferation and distribution of stress-related postnatal glucocorticoid-receptor sites localized in these brain areas. Interestingly, however, 5-HT levels in the frontal cortex of separation-stressed animals are significantly lower in adulthood than nonstressed counterparts. The authors speculate that postnatal handling, and the temporary increase in 5-HT activity produced by it, may trigger the proliferation of glucocorticoid receptors while at the same time reducing the number of 5-HT terminals in the frontal cortex and hippocampus of adult animals, perhaps by means of a 5-HT autoinhibitory signal that impedes the ontogenetic elaboration of the serotonergic system. These findings emphasize the close involvement of the serotonergic system in the modulation of stress, as well as provide a possible explanation for the efficacy of SSRIs in the treatment of stress-related disorders. SSRIs, such as fluoxetine and paroxetine, may assist affected areas of the brain to compensate for the decreased proliferation of cortical and limbic 5-HT terminals by conserving synaptic 5-HT, thereby increasing 5-HT activity and improving the overall capacity of the serotonergic system to cope with heightened stress activity resulting from increased glucocorticoid-receptor expression. Developmental and adult exposure to stress may further exacerbate the situation. In rats, chronic corticosterone administration results in the proliferation of neocortical 5-HT_{2A} receptors and an increase of a behavior anomaly specifically associated with increased 5-HT_{2A} activity known as "wet-dog shakes" (Gorzalka et al., 1998). Interestingly, melatonin has been shown to attenuate the wet-dog shakes associated with chronic cor-

ticosterone treatment, suggesting that melatonin may have some potency as a 5-HT_{2A} antagonist and potential use in some compulsive disorders associated with chronic stress.

Attention, Dopamine, and Reward

The dog's ability to orient, select, and continuously attend to changes in the environment is a critical aspect of behavioral adaptation (see *Attention and Learning* in Volume 1, Chapter 7). The orienting response is diminished or augmented by the influences of habituation and sensitization, respectively, underscoring its reflexive nature, whereas attending behavior involving the discrimination or continuous sensory tracking of events appears to be strongly influenced by instrumental contingencies of reinforcement (Catania, 1998). Both classical and instrumental attention-related activities interface along a respondent-operant axis transforming the environment into a predictable and controllable field of activity—or not (see *Defining Insolvable Conflict* in Volume 1, Chapter 9). Environmentally produced disturbances of attention have been hypothesized as playing a central role in neurotogenesis (see *Locus of Neurotogenesis* in Volume 1, Chapter 9). As a result of exposure to environments lacking predictability and controllability, attention abilities may be strained, with behavioral output becoming progressively disorganized and ineffective. As the result of chronic exposure to adverse environments, dogs may, on the one hand, become progressively vulnerable to the elaboration of compulsive rituals or, on the other, fall victim to cognitive and output deficiencies associated with learned helplessness. Under the conditioning influence of unpredictable and uncontrollable events (insolvable conflict), affected dogs may gradually acquire a negative cognitive set, whereby they come to act as though significant consequences occur independently of what they do or believe. Such dogs may simply give up and stop trying altogether. According to this general hypothesis, some compulsive rituals and impulsive behaviors may stem from an impairment of central mechanisms controlling behavior via consequences (e.g., reward and punishment) produced by it, with the net result that repetitive stereotypies and rituals displace organized and goal-oriented behavior. This is consistent with the relative resistance of compulsive behaviors to modification by the arrangement of consequences. These observations underscore the importance of providing affected dogs with training based on highly predictable and controllable outcomes, aimed at restoring a positive cognitive set and convincing such dogs that what they do makes a difference in what happens to them. In general, a history of orderly training and reinforcement results in optimism, competence, confidence, and elated mood, whereas a history of excessive and unpredictable punishment results in pessimism, increased incompetence and insecurity, depressed mood, helplessness, and increased vulnerability to behavioral disturbance.

Dopaminergic activity appears to enhance attention, positive motivation, and learning. Mills and Ledger (2001) found that dogs treated with selegiline, a DA agonist, focus significantly better on tasks and are less distracted than controls not treated with the drug. They attribute the beneficial effect of the drug to the enhancement of positive incentive. Sensory inputs that attain selective prominence and attention do so through a variety of interacting pathways. Attractive orienting stimuli (conditioned and unconditioned appetitive stimuli) appear to converge on midbrain DA neurons located in VTA (see *Catecholamines: Dopamine and Norepinephrine* in Volume 1, Chapter 3). When animals are presented with appetitive stimuli (food), DA neurons normally respond with brief, phasic activations (Schultz et al., 1997). These DA neurons are also activated by the presentation of novel stimuli eliciting an orienting response, but this pattern of activation quickly habituates unless the stimulus is followed by the presentation of food. After repeated pairings of an auditory or visual stimulus (i.e., a conditioned stimulus or CS) with food (i.e., an unconditioned stimulus or US), the onset of increased DA neuron activity occurs immediately after the presentation of the CS, with no additional DA activity being evident when the food is actually presented (see *Classical Conditioning, Prediction, and Reward* in Chapter 1). These findings

suggest that the primary locus of positive reinforcement occurs with the presentation of the conditioned reinforcer—not the ingestion of food, which appears to be of secondary importance, at least with respect to the activation of DA reward circuits. These findings help to explain the power of conditioned reinforcement to shape behavior and the potent incentive value of bridging signals (e.g., "Good", squeak, or click). The study also provides some clues regarding the neurobiology of extinction. After a predictive association is established between the CS and US, the omission of the customary US results in a significant depression of baseline DA activity, appearing precisely at the time (relative to the CS) when rewards were presented in the past (Schultz et al., 1997).

Compulsive excesses often consist of repetitive preparatory behaviors, liberated and functioning in relative independence from consummatory goals. In such cases, the preparatory action may possess more intrinsic reward value for the dog than the actual consummatory action or object itself (see *Instinctive Drift and Appetitive Learning* in Volume 1, Chapter 5; and *Contrafreeloading*, Volume 1, Chapter 5). Dogs may be disposed to develop compulsive excesses in situations where preparatory sequences are repetitively expressed without resulting in the procurement of the attractive object, underscoring the significance of conflict and frustration in the etiology of compulsive disorders. In the case of conflict, preparatory behaviors are repeatedly expressed but unable to achieve the consummatory objective as the result of building anxiety or fear. Under the influence of frustration, preparatory behaviors are repeatedly practiced but not gratified by access to the attractive object or activity. Finally, some repetitive rituals and stereotypies may be acquired as negatively reinforced behaviors, mediating the escape and subsequent avoidance of an *internal* aversive state by responding to antecedent signals originating in the body or environment. In other words, some compulsive behaviors—apotropaic rituals—may serve to ward off, delay, or attenuate an aversive psychophysiological state originating in the body—an action that may also produce significant secondary gratification associated with increased DA and endogenous opioid activity. Such rituals may evoke parasympathetic effects aimed at modifying aversive physiological states associated with stress. Tongue playing, for example, causes a significant decrease in heart rate in Japanese black calves (Seo et al., 1998). Similarly, rhythmic leg swinging produces a reduction in heart rate among children (Soussignan and Koch, 1985). Canine apotropaic rituals correspond roughly to human obsessive-compulsive rituals, but without reference to the cognitive attributes (e.g., intrusive thoughts and irrational worries).

Dopamine imbalances have been implicated in the etiology of impulse-control deficiencies in people, in association with what Blum and colleagues (1997) have called the reward-deficiency syndrome (RDS), a condition in which an organism is unable to obtain satisfying reward gratification from everyday activities. RDS presents with increased excitability and stimulus-seeking activities, hyperactivity, and compulsivity—all behavioral changes calculated to obtain increased reward gratification. Genetic studies in people and dogs show that alterations in the expression of DA receptors have a pronounced effect on temperament and behavioral thresholds. The seeking-rage axis appears to be strongly influenced by the D_4 receptor, with the short allele being associated with reduced novelty seeking, slowness to anger, and calmness (characteristic of the phlegmatic type), whereas the long allele is associated with increased stimulus-seeking behavior (novelty), compulsiveness, excitability, and lowered thresholds for anger and aggression (characteristic of the choleric type). Niimi and coworkers (1999) have found that golden retrievers and shibas predictably differ in terms of their expression of short versus long D_4 alleles, with golden retrievers being more likely to exhibit the short allele and shibas expressing the long D_4 allele more often (see *Neural and Physiological Substrates* in Volume 2, Chapter 5).

In line with the foregoing observations, training activities incorporating highly predictable and controllable events may help to enhance a dog's general behavioral effectiveness. The use of diverting stimuli and distinct

conditioned reinforcers signaling the conclusion of a simple sequence of discrete behaviors leading to positive reinforcement appears to be useful in the management of compulsive behaviors. The activation of DA activity through conditioned reinforcement of behavior incompatible with conflict and stressful arousal may exert a significant neuromodulatory effect. Once the dog is well conditioned with food, the sound of a brief tone or click produces a pronounced orienting effect while serving to activate incompatible appetitive-incentive and appetitive-seeking activities that serve to maintain continuous tracking and attending behavior. Longer-lasting olfactory stimuli, tones, or audio recordings (music) may be paired with the presentation of meals and periods of massage. Presenting novel stimuli alone also exerts a significant disruptive or diverting effect over compulsive activity, but the use of conditioned appetitive stimuli may offer significantly more powerful effects with the added advantage of providing a means for shaping behavior incompatible with the compulsive ritual. Although conditioned appetitive stimuli ("Good", smooch, click, and so forth) may produce a stronger activating effect on DA neurons than merely giving the dog food, if such conditioned stimuli are repeatedly presented without a tangible reward, the enhanced effect is rapidly extinguished. Further, as the bridge signal becomes progressively predictive of the attractive outcome, its ability to activate dopamine neurons is reduced. Dopamine reward activation depends on prediction error, such that the attractive outcome turns out to be better than expected, whereas punishment (depression of dopamine activity) results when the outcome is worse than expected. The detection of prediction error depends on a reference or standard for comparison. To optimize the benefits of reward training, the first step is to establish a control-expectancy standard based on the arrangement of highly predictable and controllable antecedent and consequent training events. In the context of such a backdrop, outcome variations can be used to produce significant changes in the activation and depression of dopamine reward-producing circuits, changes that are of considerable usefulness in the context of canine behavior therapy (see *Prediction and Control Expectancies* in Chapter 1)

Dopamine: Behavioral and Emotional Regulatory Functions

Growing evidence suggests that stress-related modifications and imbalances of dopaminergic activity profoundly influence cognitive and emotional competence in such diverse areas as selective attention and gating functions, information processing (comparator functions, expectancies, and establishing operations), impulse control, and regulation of emotional behavior (Pani et al., 2000), and compulsive behavior. These various functions are vital aspects of adaptive learning and adjustment. Under adaptive conditions, a network of coordinated interactions between phylogenetically ancient neural substrates and more recent elaborations are integrated to achieve a harmonic organization conducive to adaptive success. Under adverse conditions of escalating stress and disorganization, this harmonic organization may become unstable or break down, thereby liberating primitive defense reactions and abnormal behaviors, ranging from compulsive excesses to impulsive aggression. DA imbalances at the level of prefrontal cortex may significantly impair a dog's ability to cope with stressful situations and to exercise effective executive control over subcortical impulses. Instead of responding in a functional and adaptive way, stress-perturbed prefrontal influences may result in a persistent failure of the dog to respond normally to frustration- and anxiety-producing stimuli, leading to over- (compulsive) or under- (hyperactive) impulse-control impairments (compulsive-impulsive spectrum). DA dysregulation of prefrontal glutamatergic circuits projecting to the striatal complex has been proposed as playing a differentiating role in the etiology of hyperactivity and obsessive-compulsive disorders (Carlsson, 2001) (see *Hyperactivity and Neurobiology*).

PHARMACOLOGICAL CONTROL OF COMPULSIVE BEHAVIOR

A prominent theory suggests that CBDs are primarily the result of disturbances affecting

the 5-HT system—a position supported by the clinical efficacy of medications that enhance 5-HT function in the treatment of canine compulsive disorders. SSRIs appear to be most effective in cases where the compulsive behavior is associated with evidence of stress and adverse emotional concomitants (e.g., anxiety). For example, among bank voles exhibiting captivity-induced stereotypies (backward somersaults), citalopram, a potent and highly selective SSRI, showed no effect until acute stress was induced, whereupon a sharp increase in compulsive activity was observed. With the onset of acute stress, citalopram produced a significant modulatory effect over the frequency of motor stereotypies (Schoenecker and Heller, 2001). Animals trained to work under stressful reinforcement schedules may also exhibit a variety of behavioral excesses. Rodents working for food presented on a fixed–interval schedule (1 to 3 minutes), show a variety of behavioral excesses [e.g., polydipsia (Falk, 1971), wood gnawing (Roper and Crossland, 1982), and paw licking (Lawler and Cohen, 1992)]. Woods and colleagues (1993) have shown that schedule-induced polydipsia is significantly reduced by SSRIs (fluoxetine, clomipramine, and fluvoxamine). Adjunctive behavior has been proposed as an experimental model of compulsive behavior (see *Adjunctive Behavior and Compulsions* in Volume 2, Chapter 5).

Significant evidence suggests that SSRIs can be effectively used to manage excessive licking, especially licking that results in local lesions of the skin known as lick granuloma or acral lick dermatitis (ALD). In hopes of obtaining an animal model for investigating human OCDs, several research psychiatrists have investigated the efficacy of SSRIs in the treatment of canine excessive licking. Judith Rapoport and colleagues (1992) at the National Institute of Mental Health (Bethesda, MD) were the first to conduct sound experimental trials to evaluate the efficacy of clomipramine and fluoxetine to control the excessive licking associated with ALD. The researchers found that clomipramine, fluoxetine and, to a lesser extent, sertraline significantly reduced the frequency of compulsive licking exhibited by dogs diagnosed with ALD (N = 37), thereby confirming previous results of an exploratory study indicating that clomipramine exerted a beneficial effect in the treatment ALD (Goldberger and Rapoport, 1991). More recently, Wynchank and Berk (1998), working with a larger sample of dogs (N = 58), have reported similar benefits resulting from the use of fluoxetine therapy. A pilot study performed by Stein and colleagues (1998) has indicated that citalopram may also be effective in the control of excessive licking, with 66.7% of the dogs treated (N = 9) showing significant improvement. In addition to demonstrated efficacy for the management of ALD, clomipramine appears to reduce tail chasing in dogs (Hewson et al., 1998; Moon-Fanelli et al., 1998; Seksel and Lindeman, 2001). The beneficial effects of SSRIs for controlling canine compulsive disorders appear to be confined to amelioration rather than cure, emphasizing the importance of concurrent behavior therapy.

Although SSRIs frequently help to ameliorate the magnitude and frequency of compulsive behaviors, they are not likely to produce a complete suppression of the target compulsive activity. For example, Rapoport and colleagues (1992) found that the SSRIs studied reduced compulsive licking by less than half in comparison to baseline measures: clomipramine (43%), fluoxetine (39%), and sertraline (24%). Only two dogs (N = 37) showed a complete remission of symptoms, and both dogs were treated with fluoxetine. This pattern of partial efficacy is comparable to the therapeutic effects of SSRIs in the treatment of human OCD. In the case of refractory OCD in human patients, fluvoxamine in combination with haloperidol, a D_2 antagonist, has been proven effective for the treatment of resistant OCD symptoms presenting with comorbid tics (McDougle et al., 1994). The interaction between 5-HT reuptake inhibitors and haloperidol appears to synergistic. For example, 5-HT-enhancing drugs have been shown to potentiate the ability of haloperidol to block DA receptor activity in the rat striatum (Sugrue, 1983). McDougle and colleagues (2000) have also found that risperidone (a potent antagonist of $5\text{-}HT_{2A}$ and DA_2 receptors) in combination with fluvoxamine is effective in the treatment of refractory OCD, with or without tics. In

addition to efficacy, a major advantage of risperidone as a treatment adjunct is that it appears to produce fewer adverse side effects than observed in the case of haloperidol.

Other veterinary clinical protocols have targeted the opioid system. The suppressive effects of opioid antagonists (e.g., naloxone, naltrexone, and nalmefene) on compulsive habits have been clinically demonstrated in dogs (Brown, 1987; Dodman et al., 1988; White, 1990; Shuster and Dodman, 1998). Opioid antagonists have been found effective for reducing excessive self-directed licking (Dodman et al., 1988; White, 1990). In a clinical study involving 11 dogs with ALD, over 70% exhibited significant improvement when treated with naltrexone (White, 1990). Adverse side effects were minimal, with only one dog showing drowsiness and social withdrawal symptoms. One report, however, has noted the occurrence of significant dermatologic side effects (acute, intense, and generalized pruritus) in a dog treated with naltrexone (Schwartz, 1993). Brown (1987) found that naloxone proved efficacious in the control of tail chasing in a bull terrier, whereas phenobarbital was ineffective. Control over tail chasing was maintained by combining pentazocine (a mixed opioid agonist-antagonist) and naloxone. After 18 months of treatment, the owners reported that tail chasing rarely occurred, so long as the medication was maintained. Blackshaw and colleagues (1994) have evaluated a variety of regimens (e.g., synthetic progestins, diazepam, and naloxone) for the treatment of refractory tail chasing. An emaciated bull terrier treated with naloxone showed significant improvement while on the medication. The dog was also given a narcotic drug (meperidine), whereupon it became more agitated and lunged at its shadow. All of the dogs (N = 32) were ultimately euthanized. Dodman and colleagues (1996) have reported that several bull terriers with tail-chasing stereotypies (N = 6) and other behavior problems [e.g., unprovoked aggression (N = 1) and intense fear (N = 1)] were affected by seizures (epileptiform spiking) and varying degrees of hydrocephalus. The electroencephalograms of all of the dogs tested were abnormal. Phenobarbital showed some efficacy in four of the tail-chasing dogs and the one dog exhibiting extreme symptoms of fear. Phenobarbital treatment of tail chasing may produce an increased risk of aggression associated with episodes (Dodman et al., 1993 and 1996). At the moment, the drug treatment of choice for the control of compulsive licking or tail chasing is clomipramine or fluoxetine (Landsberg, 2001).

Note: The foregoing information is provided for educational purposes only. If considering the use of medications to control or manage a behavior problem, readers should consult with a veterinarian familiar with the use of drugs for such purposes in order to obtain diagnostic criteria, specific dosages, and medical advice concerning potential adverse side effects and interactions with other drugs.

Potential Dietary Treatments

Serotonin production and activity may be modified via dietary means and supplementation. Diets low in protein content (e.g., 16% to 18%) and high in carbohydrate levels appear to facilitate improved transport of the 5-HT precursor tryptophan through the blood-brain barrier (see *Diet and Enhancement of Serotonin Production* in Volume 1, Chapter 3). Tryptophan supplementation has been suggested as a possible treatment alternative for the management of compulsive behavior in horses (Luescher, 1998). Another potentially valuable way to improve 5-HT metabolism involves treatment with 5-hydroxytryptophan (5-HTP). Unlike tryptophan, 5-HTP freely passes through the blood-brain barrier and bypasses a critical rate-limiting step in the metabolism of 5-HT; also, it is readily available for purchase over the counter, unlike tryptophan (see *Nutrition and Aggression* in Volume 2, Chapter 6). Finally, some evidence suggests that inositol may provide a significant therapeutic effect in the treatment of human depression, panic disorder, and OCD. In a double-blind crossover trial, OCD patients (N = 13) not effectively treated with SSRIs were given inositol or placebo for a 6-week period (Mendel et al., 1996). The results indicate that inositol exerted a significant benefit, comparable to that produced by fluvoxamine and fluoxetine. Chronic treatment with inositol has also been shown to reduce behavior associated with

anxiety and depression in rats, with some evidence indicating that inositol may exert a strong attenuating effect over anxiety following acute stress (Einat and Belmaker, 2001).

DIAGNOSTIC CONSIDERATIONS

Inclusion Criteria

A variety of criteria have been suggested to assist in the formal diagnosis of compulsive disorder in dogs. A study by Hewson and Luescher (1999) was performed to validate some of these diagnostic criteria. They compared the diagnoses made by an animal behavior expert with diagnoses based on a set of formal criteria. The owners of dogs (N = 84) with possible compulsive disorders were interviewed on two separate occasions. The first interview involved the completion of a behavior-history questionnaire, with the diagnosis of compulsive disorder requiring that the dog satisfy seven formal criteria (Table 5.1). A veterinary behavior expert whose diagnosis was based on clinical experience performed the second interview. The resulting statistical analysis showed a surprising lack of diagnostic agreement between the two methods. Of 60 dogs providing sufficient information to apply the seven formal criteria, there was agreement between the formal diagnosis and the expert's opinion in only 20% of the cases. Among these 12 cases of agreement, eight agreed on the absence of compulsive disorder and four agreed on the presence of compulsive disorder. Among the 48 cases in which disagreement occurred, 12 dogs diagnosed with compulsive disorder by the expert were excluded as not having CBD by the absence of all three formal inclusion criteria believed to be highly significant (see criteria 3, 4, and 5 in Table 5.1). Other dogs diagnosed with CBD by the expert but excluded as not having CBD by formal diagnostic criteria, included 13 dogs that met criterion 3, three dogs that met criteria 3 and 4, six dogs that met criteria 3 and 5, on dog that met criterion 4, eight dogs that met criterion 5, and five dogs that met criteria 4 and 5. Among those dogs (N=4) presenting with signs matching all three formal diagnostic criteria, there was complete agreement between the inclusion criteria and the expert's opinion regarding the diagnosis of CBD. Taken together, the lack of correspondence between the expert's diagnosis and formal diagnostic inclusion criteria suggests that the process of diagnosing such behavior problems involves a great deal of contingent fuzziness and subjective judgment.

The finding of a significant independence between the two methods of diagnosis with respect to the presence of conflict and contextual generalization is surprising, given the prominence attributed to conflict and frustration in the etiology and situational generalization of compulsive disorder (Hewson and Luescher, 1996). Even so, as a diagnostic inclusion criterion, a history of precipitating conflict and frustration is problematic, not because it lacks etiological significance, but simply because the owner may not be aware of such an influence (Wynchank and Berk, 1998). Undoubtedly, behavioral conflict and stress play an important role in the etiology and maintenance of many compulsive behavior problems, but some influence other than conflict and stress is obviously at work and

TABLE 5.1. Formal criteria for diagnosing compulsive behavior disorder (Hewson et al., 1999)

1. The dog has normal findings on physical examination.
2. The dog shows compulsive behavior (e.g., tail chasing, air snapping, and excessive licking).
3. Conflict or frustration is associated with the etiology of the behavior or present in a current situation (e.g., conflict, separation anxiety, inadequate stimulation, physical restraint, or social change).
4. The number of contexts in which the compulsive behavior has increased since it was first observed.
5. The frequency of the behavior has increased since it was first noticed.
6. The behavior is not dependent on conditioning and occurs both in the owner's presence and absence.
7. The behavior is not due to seizure activity.

needs to be clarified to complete the picture. A major problem with the conflict hypothesis is that conflict and frustration are ubiquitous and commonplace but compulsive stereotypies are comparatively rare. Why do some dogs develop compulsive stereotypies while the vast majority do not?

First and foremost, there is probably a genetic predisposition involved, and perhaps a specific genetic marker may be eventually identified to help predict, diagnose, and prevent compulsive stereotypies and related adjustment problems. Of course, this is all speculative at the moment, but such a genetic marker may not be too far off in the future. One potential candidate involves genetic variants associated with the expression of dopamine receptors (see *Attention, Dopamine, and Reward*). Among humans, individuals expressing the A_1 allele for the D_2 receptor (particularly those homozygous for it) are significantly more likely to show adjustment problems in association with impulsive and compulsive behavior (Blum et al., 1997). The A_1 allele reduces the expression of the D_2 receptor up to 30% in comparison to individuals expressing the A_2 allele, perhaps significantly impeding the carrier's ability to normally experience reward and respond to reward signals. Another potential marker of interest involves the long and short alleles expressing the D_4 receptor. Among humans, the long allele is associated with novelty seeking, compulsive-impulsive behavior, excitability, and aggressiveness, whereas the short allele is associated with hesitation, reserve, and tolerance (slow to anger) (see Ebstein et al., 1996).

According to this hypothetical model, dogs prone to compulsive behavior involving a strong locomotor and aggressive component (e.g., tail chasing) would be most likely to express a dopamine-receptor profile consistent with the choleric temperament (e.g., A_1 and long alleles). On the other hand, dogs showing self-directed compulsive behavior (e.g., licking) would be most likely to express a dopamine-receptor profile consistent with the melancholic temperament (e.g., A_1 and short alleles). Finally, dogs expressing the A_2 allele in combination with the long or short alleles for the D_4 receptor would tend to differentially exhibit propensities consistent with the sanguine (e.g., A_2 and long alleles) and the phlegmatic (e.g., A_2 and short alleles) types. These four types, corresponding to Pavlov's typology (see *Experimental Neurosis* in Volume 1, Chapter 9), are hypothetically differentiated by their relative sensitivity to signals of reward and punishment (risk and loss):

Adaptive types

Sanguine (stable extravert) or s-type: Preferentially sensitive to signals of reward, much less so toward signals of successful avoidance; prone to adaptive approach.

Phlegmatic (stable introvert) or p-type: Preferentially sensitive to signals of successful avoidance, less so toward signals of reward; prone to adaptive hesitation.

Reactive types

Choleric (unstable extravert) or c-type: Preferentially sensitive to signals of loss, much less so toward signals of threat; prone to reactive frustration.

Melancholic (unstable introvert) or m-type: Preferentially sensitive to signals of threat, less so toward signals of loss; prone to reactive fear (see Figure D.1 in Appendix D).

Dogs showing a heightened sensitivity to signals of punishment, falling along the choleric-melancholic spectrum, are generally predisposed to respond to stressful conflict and frustration by reacting (e.g., attacking, repeating, persisting, or withdrawing). Conversely, dogs showing a heightened sensitivity to signals of reward, falling along the sanguine-phlegmatic spectrum, are generally predisposed to respond to stressful conflict and frustration by adapting (e.g., approaching, searching, experimenting, and waiting). According to this hypothesis, dogs fitting the choleric-melancholic profile are more prone to develop compulsive stereotypies as the result of stressful conflict educing frustration (c-type) and anxiety (m-type). The relatively fearless c-type may respond paradoxically to punishment. In such cases, rather than suppressing ongoing compulsive activity (e.g., tail chasing), punishment may increase it. C-type dogs appear to be vulnerable to vicious circle behavior, responding to signals of punishment by increasing behavioral output rather than inhibiting it (Melvin, 1971).

Excessive or inappropriate punishment or early trauma and stress may sensitize s- and p-type dogs to signals of punishment, causing them to become progressively vulnerable to develop reactive elaborations consistent with c- and m-types. Such reactive s-type dogs are often highly sensitive to both reward and punishment signals and may show extremes of intrusive playfulness and excitability, on the one hand, and inhibition and withdrawal, on the other, with little else in between. Under the influence of excessive punishment, s- and p-type dogs may become progressively unstable and reactive to signals of punishment (threat and loss), making them more vulnerable to develop compulsive stereotypies and other adjustment problems. The disruptive sensitization and polarization of behavioral approach and inhibition systems are hypothesized to result in the dysregulation of adaptive functions (see Gray, 1994), causing the dog to become inappropriately reactive to signals of reward and punishment. The alternating bipolar impulsive excitability and depressive inhibition exhibited by reactive s-type dogs is resolved by therapy efforts aimed at reintegrating behavioral approach and inhibition systems via orderly and consistent reward-based training and play. A significant function of cynopraxic training and therapy is to promote social exchanges that reliably succeed in producing reward signals in the context of reducing interactive conflict and tension. As a result of such training, maladaptive reactivity and adjustment problems are often ameliorated or resolved while at the same time improving the human-dog relationship.

Exclusion Criteria

Differential diagnosis should distinguish compulsive behavior from transient responses to conflict, learned behaviors, and behavioral sequela associated with disease. Although stereotypical activity resulting from medical conditions (e.g., partial onset seizures) is excluded, some physical injuries and traumas may set the stage for the subsequent development of compulsive behavior. Wynchank and Berk (1998) reported that although most owners could not give a reason underlying their dogs' excessive licking, 22.4% of the dogs (N = 58) began licking after a trauma or injury to the affected area. The comfort and anxiety reduction derived from repetitive licking on an injury may establish a network of conditioned associations linking the action of licking with the elicitation of feelings of comfort and safety. As a result of the intrinsic gratification produced by licking, it may be emancipated from the original function of soothing an injury to become a generalized strategy for coping with aversive emotional arousal. Emotional distress (frustration and anxiety) is essentially an aversive state involving the loss of comfort and safety. Signals of loss and suspense may function as establishing operations activating episodes of licking behavior. Licking itself may be maintained by enhanced feelings of comfort and safety, on the one hand, and an incentive to avoid signals (internal cues) portending loss and uncertainty, on the other. In short, excessive licking is an escape or brief vacation from stressful arousal. In addition to physical injuries and trauma, excessive licking may develop in association with allergies, foreign objects, arthritis, and infections (Veith, 1986) and possibly with hypothyroidism (Aronson, 1998). As the medical cause of excessive licking is discovered and treated, the licking activity may simply stop; however, in some cases, the licking may continue and become a compulsive activity.

Air-snapping behavior, an activity giving the appearance of biting at flies, has been attributed to sensory hallucinations (Voith, 1979) and vitreous floaters, that is, particulate matter suspended in a gel-like substance behind the lens of the eye (Cash and Blauch, 1979), but no clinical evidence has been reported to date establishing such a causal relationship. Another hypothesis suggests that some cases of air snapping may stem from food sensitivities or allergic reactions affecting central nervous system activity (Voith, 1979). For example, Brown (1987) reported a case (a 1-year-old, male, cavalier) in which air snapping was rapidly resolved by feeding the dog a low-protein diet consisting of fish and milk proteins. When again fed red meat, poultry, or rabbit, the air-snapping activity recurred. This report gives some support, albeit anecdotal, to the notion that food sensitivities or allergies may contribute to the development of certain stereotypies. Behavioral stereotypies

involving episodic air snapping (Voith, 1979), tail chasing (Dodman et al., 1996), and air snapping with excessive licking (Crowell-Davis et al., 1989) have been linked to focal seizure activity. Although partial onset seizure activity may be an occasional factor in the development compulsive behavior, it appears to be relatively rare. Nonetheless, such possible causes should be excluded, along with other medical problems that might adversely affect the dog's behavior and hamper therapy efforts. The exclusion of medical causes requires a veterinary examination and appropriate diagnostic testing.

EVALUATION, PROCEDURES, AND PROTOCOLS

The treatment of compulsive behavior combines a variety of behavior-modifying strategies. The selection of specific techniques depends on a number of factors, including the severity of the compulsive behavior and the owner's ability to comply with the recommendations. In all cases, it is valuable to obtain a thorough history and medical background. Since environmental deficiencies and stressors appear to play a role in the etiology of compulsive excesses, it is necessary to evaluate such influences and make recommendations based on a subjective assessment of each situation. If environmental sources of significant conflict, stress, or frustration are identified (e.g., separation-related distress, excessive crate confinement, disorderly training, or mistreatment), efforts to reduce or eliminate such influences should be considered (see *Compulsive Behavior Problems* in Volume 2, Chapter 5). In many cases, an environmental cause is not readily identifiable, suggesting the involvement of a biological mechanism or an internal cue controlling compulsive behavior in response to generalized or conditioned frustration or anxious arousal (see *Assessment and Evaluation* in Volume 2, Chapter 5).

Many compulsive dogs are highly active and usually benefit from additional vigorous exercise, especially activities involving physical exertion but requiring a high degree of attentional focus and impulse control. Ball and flying-disk play, agility exercises (weave poles and jumps), and play-oriented obedience training may also be beneficial. Situations evocative of stress-induced compulsive behavior should be avoided as much as possible, unless ongoing behavior-therapy efforts are in place. Although many compulsive behaviors respond to behavior therapy, some pathological compulsions may persist despite the most conscientious training efforts, suggesting the presence of neurobiological disorder and the need for adjunctive pharmacological intervention. Finally, some compulsive behaviors may be a nuisance or aesthetically displeasing but not harmful to the dog. For example, sucking, kneading, and licking compulsions directed toward inanimate objects (e.g., blankets or flooring) are often best left alone unless the compulsive behavior results in damage or harm to the dog.

In addition to general contextual and motivational factors, information concerning specific triggers, the frequency of the behavior, and its duration, and time and place should be noted. Information about persons present and their proximity to the dog as well as ongoing activities should be explored. Of particular importance is the ease with which the dog can be distracted from the activity and the interval between recurring bouts. Compulsive behaviors and rituals that can be easily interrupted are typically more responsive to behavior-therapy efforts. Stereotypic repetitive behaviors that cannot be safely interrupted or that require physical restraint to stop may benefit from pharmacological intervention in conjunction with intensive behavior therapy and training efforts. By combining behavior and drug therapy approaches, there is a better likelihood of achieving more durable changes when the medication is discontinued.

Together with the objective of resolving specific complaints, counseling and therapy activities should be performed with cynopraxic goals in mind (see *Cynopraxis: Training and the Human-Dog Relationship* in Volume 1, Chapter 10). From the cynopraxic perspective, the behavioral complaint is an opportunity for owners to enhance their relationship with the dog and to improve the dog's quality of life. Ostensibly, the behavior problem brings the trainer and dog owner together for the purpose of modifying the dog's behavior, but the true intent and measure of success for cynopraxic counseling and therapy efforts is

the furtherance of cynopraxic bonding and quality of life objectives. As the result of such emphasis, even in cases where training efforts are not entirely successful in the short-term, a significant benefit is nonetheless achieved by fostering a better understanding of the problem and helping the owner to better cope with it. In addition to increasing the owner's appreciation of the dog's needs, the training and management skills acquired by the owner lay the groundwork for the long-term improvement or successful resolution of the problem as well as facilitating a more fulfilling and rewarding experience of the dog as a companion and family member.

Diversion and Disruption

Some compulsive behaviors can be effectively managed with the use of diverters and disrupters aimed at interrupting the compulsive sequence (see *Diverters and Disrupters* in Volume 1, Chapter 7). For example, tossing a ball just as the dog begins to chase its tail can be a useful diversion. Subsequent access to the toy can be made contingent upon the absence of the tail-chasing behavior. In addition to the presentation of play objects, target-arc training can be used to generate an effective diverter stimulus (squeaker, smooch, or whistle) having considerable value in the context of treating CBDs (see *Attention and Play Therapy* in Chapter 8). Savory treats can also be used to divert the dog from the compulsive ritual and to subsequently reward attending behavior or to reinforce actions incompatible with the compulsive habit. Since the dog is not performing the ritual with the purpose of controlling access to food, the provision of food as a diversionary stimulus is not likely to strengthen the undesirable compulsive behavior. Instead the diversionary presentation of food functions as an establishing operation that is more likely to set the occasion for the dog to show behavior incompatible with the compulsive action, that is, actions that enabled the dog to successfully control food-sharing exchanges with the owner in the past (e.g., attentive (begging and simple obedience modules). Disrupter-type stimuli can also be useful, especially in cases where diverters are not effective alone or in cases where the dog resumes the compulsive excess after being diverted from it. A rolled sock or one containing a small amount of popcorn and knotted is very effective in the case of mild compulsive behaviors. The sound of throw rings thrown near the dog can rapidly acquire a conditioned inhibitory effect, subsequently making them effective when tossed up and down in the hand. Similarly, a shaker can, push-button alarm, or compressed-air device can be effectively used for such purposes.

Response Prevention, Interruption, and Shaping Incompatible Responses

When excessive repetitive behavior is associated with a specific environmental event or situation, the first step, whenever possible, is to modify the environment in order to eliminate such adverse influences. In cases where environmental modification is not possible, the dog's response to the stimulation must be modified. Compulsive rituals unresponsive to interruption efforts may benefit from response-prevention techniques. During response prevention, the compulsive behavior is blocked by various means, including physical restraint. Exposure with response prevention has been proven to be effective in the treatment of a variety of human OCDs. Chasing shadows and flecks of light are common behavioral excesses among highly excitable and reactive dogs. The origin of such compulsions can often be traced to teasing games involving flashlights or laser pointers. Such behavior can be highly disruptive and disturbing, especially if it is associated with barking or destructive behavior. Since specific classes of stimuli consistently evoke such behavior, they are typically highly responsive to exposure with response prevention, counterconditioning, differential reinforcement of incompatible behavior (DRI), inhibitory training using disrupter stimuli (e.g., a modified carbon-dioxide pump or shaker can), and time-out (TO) procedures. In extreme cases, however, such behavior can be highly persistent and resistant to behavior-control strategies. For example, in one case, an English bulldog developed a highly stereotypic and compulsive aggression ritual in response to lights being turned on. The dog jumped, barked, and snapped at ceiling lights until they were turned off or until becoming physi-

cally exhausted. The ritual was extremely energetic, persistent, and aggressive. Any efforts to restrain the dog during such episodes resulted in redirected aggression, making treatment efforts dangerous and unproductive. The dog had undergone veterinary testing and treatment, including various antiseizure medications, to no avail.

Leash prompts and directives leading to the reinforcement of alternative behaviors can be helpful as a means to interrupt and diminish compulsive excesses that habitually occur in the owner's presence. For example, a dog that engages in excessive licking can be kept on a leash and collar or halter at times when it is likely to lick. When licking occurs, the action is interrupted by saying "Stop" and directing the dog's mouth away from the licked area by pulling on the leash. The licking dog can also be trained to perform an incompatible response via DRI training, such as turning its head away from the licked area on signal, perhaps redirecting the dog's interest toward a toy. A clicker can be used to bridge the occurrence of the incompatible response with a food reward or toy. In cases where the compulsive behavior occurs at a high rate, differential reinforcement of other behavior (DRO) can be introduced (see *Differential Reinforcement of Other Behavior* in Volume 1, Chapter 7). The DRO procedure provides contingent reinforcement based on the absence of behavior during some fixed or variable length of time. The primary criterion for reinforcement to occur is that the dog refrain from the compulsive activity during the preset DRO time period. An advantage of the DRO technique is that it provides a high frequency of reward and support for a variety of alternative behaviors occurring in the absence of the compulsion, more specifically those behaviors whose occurrence happens to coincide with the offset of the DRO period. Eventually, as the rate of compulsive activity is reduced, a response incompatible with licking can be brought under the control of a DRI schedule.

Bringing the Compulsive Habit Under Stimulus Control

A common complaint involving compulsive attention seeking is excessive pawing directed at family members or guests—a social excess that is prevalent among golden retrievers. Social pawing, which can be a persistent habit that resists corrective efforts, is most commonly exhibited in situations in which a dog is conflicted by opposing motivations between attention-seeking needs and unstable boundaries established to control excesses associated with it. Pawing has a controlling and obnoxious quality about it that becomes especially evident and transparent if the owner or guest attempts to stop or restrain the dog while it is performing the attention-seeking excess. Direct punishment is not recommended because of the social nature of the behavior, and many owners are justly reluctant to punish such behavior. Extinction (ignoring the behavior) is of little value for controlling such excesses.

An effective approach for resolving this problem involves bringing the pawing behavior under stimulus control. The first step is to reinforce every pawing action with the presentation of food. As the dog learns that its pawing action turns on the presentation of a treat, a vocal signal like "Paw" or "Shake" can be overlapped with the action or just slightly in anticipation of it. Once the behavior is actively under the control of the vocal signal, pawing actions that occur off cue are ignored, blocked, or suppressed by TO (the owner gets up and walks away). Pawing action occurring off cue is followed by "Stop." If necessary, progress can be facilitated by employing a response-prevention procedure, whereby a leash is used to shift the dog's weight toward the side left unsupported during pawing actions. Another method is to grasp the dog's paw and hold it firmly but without producing discomfort. At the moment when the struggle to break the control reaches a peak, the paw is released as the owner shouts "Stop." This procedure is repeated every time the dog extends his paw. Grasping the dog's paw is mildly aversive, while the act of successfully withdrawing it is negatively reinforced. By shouting the word signal "Stop" at the moment of release, the signal is associated with the subsequent paw-withdrawal behavior. As the signal becomes conditioned, it can be used to interrupt future pawing efforts. Despite conscientious training efforts, it is sometimes necessary to interrupt the behavior with an appropriate disrupter stimulus (e.g., low-pressure compressed air) or the presentation of a

scent previously paired with a compressed-air startle.

Once a dog hesitates and inhibits pawing, the owner should challenge-dare the dog by slapping a knee and delivering the words "Do you want!" in a forbidding tone of voice. The challenge-dare provokes a conflictive choice point, whereby the dog is tempted to paw but hesitates and chooses not to paw in deference to the owner's forbidding tone. If the dog resists the challenge-dare temptation, the appropriate hesitation and choice is rewarded with affection and an opportunity to give its paw on command, "Paw." The pawing response is subsequently stopped with the command "Stop" and the dog's compliance rewarded with food and petting. If the dog fails to stop or attempts to paw off-cue it is diverted, reprimanded, restrained, or timed out, as appropriate.

Excessive Licking and Tail Chasing

Excessive Licking

A dog's excessive licking directed toward its body or inanimate objects (e.g., floor, carpeting, or furniture) is a relatively common compulsive habit. Since licking is often secondary to a variety of medical causes, it is crucial that a veterinary differential diagnosis be performed to exclude such factors and provide necessary treatment. Licking excesses that result in hair loss and sores (e.g., ALD) to the extremities are best approached by the application of a combination of behavioral techniques, selected on the basis of a dog's needs and response to therapy. Modifying social and environmental sources of stress and conflict can be helpful but rarely completely resolve the problem. If licking activity is found to occur in association with an identifiable stimulus, a process of graduated exposure in conjunction with counterconditioning or exposure with response prevention might be helpful. Distracting the dog or prompting and reinforcing alternative activities incompatible with the compulsive activity may also be beneficial (e.g., fetching a toy). Excessive licking toward the body or inanimate objects often occurs when the dog appears relaxed and when little else is going on in the household (Hewson et al., 1998)—a finding that seems to suggest that such dogs lick to obtain stimulation or to comfort themselves. In such cases, supplemental massage, play, and exercise may be particularly beneficial.

A scented squeaker can sometimes be effectively used to control excessive licking. The compound squeak-and-odor stimulus is delivered at the earliest moment in the licking sequence, causing the dog to turn away from the licked area and direct its attention toward the trainer. In mild cases, the squeaker-odor combination alone may be sufficient to interrupt licking, especially in cases where the odor has been previously associated with play and posture-facilitated relaxation training. In cases requiring more control, a previously conditioned click is used to strengthen behavior that turns the dog's attention away from the licking site. Initially, the dog's orienting response to the squeaker is immediately bridged with a click and food reward. As the training process proceeds, a variable DRO schedule of reinforcement is introduced requiring that the dog not orient back toward the site of licking for some varied period followed by the click and food reward. The size and type of the food reward should be varied to maximize its reinforcement effect. Although any response other than licking is reinforced at the conclusion of the DRO period, gradually the licking behavior can be channeled into some other activity (e.g., licking peanut butter from a hollow rubber toy). Also, DRO scheduling can be followed by a series of attention and basic training exercises reinforced with food, petting, and play. The DRO schedule generates a reward-dense training situation that is highly compatible with a variety of TO procedures. For example, if a dog licks before the end of the DRO period, the schedule can be reset following a brief TO, during which licking is prevented or blocked and rewards are withdrawn for 30 seconds or so.

Many compulsive licking habits do not occur reliably under the elicitation of specific social or environmental stimuli that can be controlled or changed. For example, excessive licking activity sometimes develops in association with separation distress or boredom (i.e., frustration of the seeking system). Also, some compulsive licking may be performed as an

apotropaic ritual and maintained by the anxiety-reducing effects produced by the activity. So long as the dog is able to perform the repetitive action, it will not likely adopt other ways to cope with stress. Consequently, it is often necessary to block or prevent the licking behavior by physical restraint. In mild cases, covering the area with an elastic bandage can be a useful way to prevent licking when the owner is absent. Alternatively, in more severe cases, the dog may need to be fitted with an Elizabethan collar to prevent licking activity. When the owner is present, a leash and collar, halter, bandaging, or muzzle can be used to prevent the dog from licking or performing similar compulsive behaviors. The dog should never be left alone while wearing a leash, halter, or muzzle. Muzzle restraint can be applied contingently in response to licking episodes. If the dog licks and fails to respond to the interruption signal "Stop," the muzzle is placed on the dog. After a brief period of response prevention, the muzzle is removed, and the dog is given an appetizing chew toy (e.g., a rubber toy slathered inside with peanut butter) used to redirect licking activity. In this case, licking turns on muzzling while not licking turns it off—a contingency that may gradually help to reduce compulsive licking. At such times, massage and the presentation of an olfactory stimulus (e.g., orange, chamomile, or lavender) previously associated with safety and relaxation can be used to support arousal incompatible with anxiety. Diffusing an olfactory safety signal (OSS) into the room may also yield some benefit (see *Olfactory Conditioning* in Chapter 6).

In the case of refractory or self-mutilative compulsions, the trainer might consider various aversive counterconditioning and aversion-relief procedures. In general, aversive procedures should be applied only after less intrusive and nonaversive methods have failed. In some cases, a repellent may be applied to the licked area or to bandages, but such approaches do not appear to be very effective. Another approach that may be more effective involves the use of a taste-aversion procedure (Gustavson, 1996). Many studies have demonstrated the efficacy of taste aversion for inducing a lasting repulsion toward tastes and foods associated with nausea (see *Taste Aversion* in Volume 1, Chapter 6). In this case, a novel tasting substance is applied to the licked area. After licking the treated area, the dog is exposed to a nausea-producing agent. It is reasonable to suppose that taste-aversion therapy might produce a lasting repulsion toward the substance, perhaps sufficient to deter the dog from licking on areas treated with it. To my knowledge, this procedure has not been tested for efficacy, but it would seem to represent a possible means for controlling severe and refractory self-mutilative behavior. It should be noted, however, that the viability of taste aversion for controlling canine appetitive behavior has not proven to be very effective or durable, and the procedure is not free of potential undesirable side effects (see *Tolerance for Nausea and Taste Aversion* in Volume 2, Chapter 9).

Although various remote startle devices (e.g., shaker can, compressed air, and alarm devices) can momentarily interrupt licking episodes, the behavior tends to recover rapidly. Compressed air delivered through a modified carbon-dioxide (CO_2)-charged air pump (see *Modified Carbon-dioxide Pump* in Chapter 2) can be scented with an odor (e.g., citronella-eucalyptus mix). After the dog is sensitized to the odor, it can be applied to the licked area to produce a more lasting effect. A brief burst of scented air is directed toward the area being lick, both startling the dog and leaving a scented reminder on the spot. The diluted scent can be subsequently applied to the area with a cotton squab. Odors previously associated with startle may directly inhibit licking or potentiate the effect of other (weaker) startling events, thereby making them more effective. A remote-activated citronella collar can be used to produce a similar result. Again, a dilute citronella scent can be applied directly to the area, taking care not get the material into open sores. Finally, a scented seven-penny shaker can is sometimes used in a similar way to disrupt excessive licking. When the can is first used, it should be tossed near the dog to produce a sensitized response to the sound and odor. After a few such exposures, a shake or rattle of the can will evoke a strong inhibitory response. Such techniques should only be used in the context of reward-based training efforts in which alternative behavior is prompted and rein-

forced after licking is inhibited (e.g., giving the dog a hollow rubber toy smeared with peanut butter).

An aversive technique that has shown efficacy for inhibiting excessive licking is remote-electrical training. Eckstein and Hart (1996) were able to suppress compulsive licking in four dogs (N = 5) after delivering an average of 12 brief shocks per dog. The suppressive effects of electrical stimulation were rapid and highly durable (see *ES and Refractory Compulsive Behavior* in Chapter 9).

Tail Chasing and Whirling

Since tail chasing often occurs in situations involving increased excitement and frustration, it may be useful to anticipate such behavior by using a response-prevention procedure or by increasing obedience control at such times. Also, some dogs may benefit from compensatory stimulation (e.g., ball play) or the presentation of various anticipatory diverters or disrupters. An orienting response to a squeaker-odor stimulus is used to interrupt whirling momentarily in anticipation of initiating a DRO procedure. A well-conditioned click and food reward can be used to support the orienting response, with subsequent clicks and food rewards following after varying brief periods of abstinence from whirling activity in accordance with DRO schedule requirements. The DRO schedule provides reinforcement after a fixed or variable interval, provided that the dog does not chase its tail. If the dog does whirl, the vocal cue "Stop" is presented and the compulsive action is interrupted, whereupon the dog is restrained to a tie-out or TO area. When interrupting tail-chasing behavior, great care and caution should be taken, since some dogs may respond aggressively when interfered with at such times. In cases where a risk of attack exists, added precautions should be taken, e.g., muzzling or keeping the dog on a leash and muzzle-type halter that produces a clamping action on the dog's jaws. During TO, the dog's leash is pinched in the doorjamb, leaving it with enough room to stand and sit but not chase its tail (response prevention). The TO should not exceed 1 minute, with 30 seconds often being sufficient. At the conclusion of TO, the dog is returned to the evoking situation and the DRO schedule reinstated. In the early stages of DRO training, the compulsion-free period should be adjusted to maximize the flow of rewards and reinforcement of behavior incompatible with tail chasing. In addition to the suppressive effects produced by the loss of food and social rewards, the contingent application of a brief TO appears to help de-arouse such dogs.

Another method of some value for the control of compulsive whirling involves bringing the behavior under stimulus control. Waving a hand in a wide circular direction above a dog's head can often evoke tail chasing. In cases were this does not initially evoke the whirling response, a vocal or visual signal can be paired with spontaneous tail-chasing events. After several repetitions, the signal itself will gradually evoke the whirling response. As the dog starts turning, a conditioned reinforcer (e.g., click) is delivered and a treat is tossed to the floor in front of the dog. If the dog stops, the training procedure is repeated; if not, the behavior is interrupted with the vocal cue "Stop" followed by appropriate disruptive stimulation (e.g., toss of a shaker can or compressed air with deterrent odor) or restraint. This pattern is repeated until the dog starts and stops whirling on signal. Tail chasing is interrupted at the earliest sign or intentional movement, whereupon the whirling response is countermanded by a response incompatible with tail chasing (e.g., stay or sit). All tail chasing or whirling off cue is either blocked or suppressed. This procedure is carried out until the dog's impulse to chase its tail is replaced by an incompatible response or reduced sufficiently to employ a DRO and TO procedure, as already described.

In cases where a dog fails to stop on signal or is unresponsive to disruptive stimuli, electronic training may be useful. Whenever remote electronic devices are used, the dog should first receive appropriate safety training. Initially, the least aversive electrical (e)-stimulus sufficient to stop tail chasing is used. During the escape phase, a continuous stimulus is applied until the dog stops whirling, at which point a conditioned negative reinforcer is delivered just before the e-stimulus is turned off. The avoidance phase is

initiated by presenting the vocal signal "Stop" just before the e-stimulus is delivered. Once the dog demonstrates an ability to control the tail-chasing behavior in response to low-level e-stimulation, a stronger e-stimulus can be introduced with the goal of suppressing it. The vocal signal "Stop" is coupled with the immediate delivery of a momentary e-stimulus set at a moderately high level. To produce an effective reminder to deter future tail chasing, a novel odor (citronella) is applied beforehand to the dog's tail or rear end. Later, the deterrent odor can be administered contingently by using a CO_2 pump sprayed in the direction of the dog's tail (see above) or via a remote citronella collar.

Automated Training

Given the common incidence of canine licking and tail-chasing compulsions, future research efforts should explore the viability of automated devices designed to detect compulsive activity and to deliver appropriate consequent events. Such devices are especially needed in the case of compulsions that occur when the owner is absent. Behavior-activated devices are in widespread use for the control of boundaries and barking excesses, providing a foundation of technology for more sophisticated behavior tools for measuring and treating behavior problems. For example, in the case of excessive licking, a pressure- or moisture-sensitive device could be programmed to detect both the absence and presence of licking, thereby keeping track of the behavior objectively. Such a device could be designed to interface with a treat dispenser for the purpose of DRO training or for shaping an incompatible response (e.g., lever pressing). The device could also be programmed to deliver lick-activated aversive stimulation as well as safety odors, thereby making the process of inhibitory training more efficacious and lasting. In the case of excessive tail-chasing and whirling compulsions, a movement-sensitive device could detect whirling movements, record their duration and frequency, and provide appropriate consequent events to promote DRO training, shape incompatible behavior, deliver whirling-contingent aversive stimulation, and the release of safety odors.

PART 2: HYPERACTIVITY AND HYPERKINESIS

Behavioral complaints involving overactivity and impulsivity are common with dogs, with certain breeds (e.g., hunting and working dogs) tending to exhibit such adjustment problems more often, suggesting that a strong genetic factor may be involved. As the result of conscious and unconscious selection pressures, hunting and working breeds have undergone various biogenetic changes conducive to working functions, including increased activity levels, low-threshold attention and orienting responses, and rapid behavioral adjustments to environmental stimulation (impulsivity). From the perspective of utility, such traits may significantly enhance the performance of hunting and working dogs. Such dogs are often required to search large areas as rapidly as possible, making traits conducive to high activity and energy of tremendous value. A high degree of excitability and rapid attentional shifting and sifting through environmental stimuli would also enhance the ability of hunting dogs to search for game. The best detector dogs are highly energetic, impulsive, and driven to locate hidden objects. Guarding dogs benefit from increased attentional shifting and hypervigilance in the detection and anticipation of potential threats. Impulsive and fearless action may serve hunting dogs in the pursuit of game and provide a significant advantage to working dogs when faced with risky or threatening situations requiring immediate and uncalculated action. Impulsive behavior is particularly advantageous in situations requiring split-second decisions. However, when comorbid oppositionality (fairly common among hyperactive dogs) and impulse-control deficiencies present together with a tendency toward rapid behavioral adjustments and fearlessness, the risk of aggression may be increased. A more common characteristic of hyperactive dogs is playfulness, with such dogs appearing to obtain pleasure from drive-related modal activity that involves environ-

mental and social exploration, novelty seeking, and the search for positive prediction error, that is, a preoccupation with reward seeking.

Although high activity and excitability levels may be desirable in the case of hunting and working dogs, such traits often result in significant disruptive behavior and training problems when expressed in the home (Voith, 1980). Hyperactive dogs often exhibit intense greeting rituals involving sustained jumping up, running about, and other behavior indicating a high level of arousal (e.g., barking and mouthing on hands and clothing). Such dogs may persist in such behavior despite repeated efforts to correct or restrain them. In addition to social intrusiveness and oppositional behavior, overactive and impulsive dogs frequently exhibit numerous control-related behavior problems (e.g., jumping on counters, destructive behavior, and reckless behavior around children). Hyperactive dogs often appear to be possessed by an insatiable desire to play and explore, grabbing virtually anything that they can get into their mouths, occasionally swallowing objects that cause gastrointestinal distress or blockage that requires veterinary treatment. When walked, such dogs often become extremely active, excited, and distracted, forcefully pulling into the leash, barking, and exhibiting various other impulsive behaviors that greatly distress their frustrated owners. These impulsive excesses on leash frequently lead to exercise and stimulation deficits simply because owners give up trying to walk and exercise them. When transported by car, overactive dogs may frantically pace back and forth, pant continuously, and bark at passersby and other dogs. These various excesses and adjustment problems almost invariably result in the use of inappropriate punishment and confinement further depriving hyperactive dogs of needed stimulation and exercise. Hyperactive dogs are exposed to excessive crate confinement or banishment to the backyard, where they dig, destroy plants and shrubbery, and engage in nuisance barking.

Although the crate can be an effective management tool, when used excessively or inappropriately it can become the hub of a vicious cycle of restraint and escalating compensatory activity and other adverse side effects. The use of a plaster cast for mending a broken arm offers an apropos metaphor for appreciating the benefits and risks of crate confinement. When used properly, the cast provides a highly beneficial effect by keeping the arm in a fixed position. However, if the cast is left on the arm for too long, significant adverse side effects will gradually overshadow its benefits, with the muscles of the arm gradually atrophying and losing strength. Similarly, the constructive use of crate confinement can be highly effective and beneficial, but if it is used as a substitute for training or employed excessively or inappropriately (e.g., as a place for time-out), crating may produce a variety of undesirable side effects (see *Dangers of Excessive Crate Confinement* in Chapter 2).

Compulsivity and Hyperactivity: Evolutionary Considerations

Compulsive disorders and hyperactivity appear to be phenomenological opposites sharing a common axis of impulse-control impairment and behavioral excess but in opposite directions. Whereas compulsive dogs appear to take pleasure in repeating certain sequences of behavior to the point of excess, hyperactive dogs appear to be intolerant of repetitive routines, showing a preference for behavioral change and novelty. Dogs tending toward compulsivity appear to be more routine oriented, whereas the behavior of hyperactive dogs tends toward a high level of variability (see *Cognitive Interpretations and Speculation* in Volume 2, Chapter 5). Compulsive dogs tend toward introversion (self-directed), avoidance of danger, and the performance of repetitive routines (phlegmatic-melancholic axis), whereas hyperactive dogs are more extraverted (other-directed), outgoing, reward seeking, fearless, and variable in their behavior output (sanguine-choleric axis). The evolutionary differentiation of traits tending in the complementary directions of compulsivity and impulsivity would provide an adaptive hedge against changing environmental circumstances. Under

stable circumstances of plenty, compulsive traits associated with repetitive tasks, routines, and security seeking would be adaptive whereas, at times of crisis and starvation, increased behavioral impulsiveness, variability, fearlessness, and tolerance for disgust would provide a significant advantage. Interestingly, hyperactive dogs often engage in pica and coprophagy, suggesting the possibility that such vices and hyperactivity may be linked by a common evolutionary function—survival under adverse conditions (see *Encoded Survival Habits* in Volume 2, Chapter 9). Hyperactive traits may serve to increase survivability during times of adversity, starvation, and upheaval, whereas compulsive traits would be more conducive to settled and relatively stable circumstances. Under highly organized and stable conditions, disruptive hyperactive behavior becomes a source of social concern and the focus of behavioral control efforts in both humans and dogs.

HYPERACTIVITY AND NEUROBIOLOGY

A dog's nervous activity can be conceptualized as resulting from the dynamic interplay of excitatory and inhibitory neurotransmitters, especially gamma-aminobutyric acid (GABA) and glutamate, respectively, operating under the modulatory influence of monoamine neurotransmitters (e.g., DA, 5-HT, and NE), a host of neuropeptides (e.g., CRF, opioids, oxytocin, and arginine vasopressin), and other psychoactive substances (e.g., lipids and fatty acids). Normally, cortical inhibitory processes actively modulate excitatory subcortical neuroactivity. The result is organized and highly regulated activity. In hyperactive dogs, cortical inhibitory processes appear to be insufficient to regulate excitatory impulses. Hyperactivity, inattentiveness, and impulsivity may persist despite repeated punishment involving both aversive stimulation and the loss of reward, suggesting that the disorder may involve an impairment of executive control functions. Current research emphasizes the involvement of frontostriatal circuits—including prefrontal and orbitofrontal areas, the striatal complex, and the anterior cingulate—in the etiology of hyperkinetic impulsivity. When functioning properly, each of these areas contribute to the expression of integrated and organized behavior, providing the when-what-where mechanisms by which dogs establish control over the environment and optimizes their ability to exploit it.

Executive impulse-control abilities only gradually acquire full functional activation and capacity (Rubia et al., 2000). Young dogs frequently exhibit hyperactivity and impulse-control problems that improve with age, implicating an ontogenetic normalization of attention and impulse-control abilities. In the case of hyperkinetic dogs, impaired or reduced cortical activity may persist, stemming from an organic impairment affecting the frontostriatal system. Carlsson (2001) has suggested that obsessive-compulsive disorder (OCD) and attention-deficit hyperactivity disorder (ADHD) are conditions that stem from the dysregulation of prefrontal glutamatergic activity. According to this hypothesis, OCD and ADHD are cognitive and behavioral antipodes, with obsessions and compulsive behavior resulting from prefrontal overactivity, whereas hyperkinetic inattentiveness and impulsivity are the result of prefrontal underactivity. Treatment with psychostimulants appears to increase prefrontal activity via dopaminergic activation of glutamate circuits, thereby normalizing function. Interestingly, normoactive dogs given D-amphetamine exhibit increased stereotypic activity (Bareggi et al., 1979), a finding consistent with Carlsson's hypothesis that cortical overactivity may underlie the elaboration of compulsive rituals. Various lines of research are currently under way to isolate the neurobiological causes of ADHD, with most theories focusing on disturbances of 5-HT and DA neurotransmission. Both serotonin and dopamine serve to modulate excitatory (glutamate) and inhibitory (GABA) systems governing emotional and motor activity (see *Neural and Physiological Substrates* in Volume 2, Chapter 5). In addition to stimulating dopaminergic activity, psychostimulants

increase alertness and cortical arousal via noradrenergic circuits.

Pharmacological Control of Hyperkinesis

Generally, hyperactivity is differentiated from hyperkinesis by identifying behavioral indicators and the performance of a stimulant-response test (see *CNS-stimulant Response Test* in Volume 2, Chapter 5) (Luescher, 1993). Unlike hyperactive dogs, hyperkinetic dogs show a paradoxical response to psychostimulant therapy; that is, instead of becoming more active under the influence of stimulants, hyperkinetic dogs become less active and impulsive and more responsive to inhibitory control (see *Hyperactivity versus Hyperkinesis* in Volume 2, Chapter 5). Psychostimulant therapy appears to reduce symptoms of human ADHD in approximately 80% of diagnosed cases (Paule et al., 2000). Although hyperactivity is common in dogs, stimulant-responsive hyperkinesis appears to be much less common in dogs than in people, but good epidemiological studies are lacking in this area. Whether the disorder is actually rare or underdiagnosed remains to be determined. Criteria for identifying impulsive and overactive dogs that may be hyperkinetic (and warrant stimulant-response testing) remain to be developed and validated. Luescher (1993) has suggested that hyperkinesis often presents with multiple and serious behavior problems.

In the past, D-amphetamine was the most common drug used to control hyperkinesis, but other medications have also been effectively used to control the problem in both children and dogs. Arnold and colleagues (1973) have compared the efficacy of D-amphetamine with L-amphetamine for the control of hyperkinesis and aggression in dogs. They found that the D-isomer was approximately three to four times more effective in the control of hyperkinesis than was the L-isomer. However, both drugs proved equally effective in the control of aggression associated with hyperkinesis. The only significant difference between the two drugs was that the effect of L-amphetamine lasted only half as long that of D-amphetamine. The most common alternative drug for the control of human ADHD is methylphenidate. Although effective and perhaps producing fewer side effects (less agitation and fewer stereotypical behaviors), the drug wears off more rapidly and does so precipitously—a potentially dangerous pharmacokinetic feature in the case of aggressive dogs (Drastura, 1992). Voith (1980) reports success using the tricyclic antidepressant amitriptyline for the control of hyperactive symptoms not responsive to central nervous system (CNS) stimulants.

Another medication that may offer some additional benefits in the treatment of hyperkinetic symptoms is clonidine, which has shown promising efficacy with children diagnosed with ADHD not responsive to CNS-stimulant therapy. The drug appears to enhance impulse control and improve frustration tolerance in overactive and uninhibited children (Riddle, 1991). When clonidine is given with methyphenidate, the combination may produce beneficial synergistic effects and be particularly useful in the treatment of impulsive aggression presenting comorbidly with hyperkinesis (Connor et al., 2000)—a potential treatment regimen that remains to be evaluated for safety and efficacy in dogs. Also, when given together, a smaller dose of methylphenidate may be required to produce a therapeutic effect.

Schnackenberg (1973) has reported that caffeine works about as well as methylphenidate in children diagnosed with ADHD. Subsequent studies were not been able to confirm these observations (Garfinkel, 1975). Krushinskii (1960), who performed several experiments exploring the effects of caffeine on excitability in dogs, arrived at two general conclusions concerning the effect of caffeine on general excitability:

> It was shown, first, that excessively large doses of caffeine, causing a sharp increase in the process of excitation, produce limiting inhibition. Consequently, the conditioned reflexes are not increased; on the contrary, they are depressed … Second, it was shown that the effect of caffeine on the process of excitation is largely dependent on the typological properties of the nervous system. In animals with a weak type of nervous

> system, administration of only small doses of the drug leads to an increase of the conditioned reflexes; larger doses depress conditioned reflex activity. Just as during weakening of the nervous system by excessive nervous strain, castration, or old age only the slight increase in excitability obtained by the use of small or average doses of caffeine leads to an increase in the conditioned reflexes. The administration of large doses depressed them. (57)

Despite these intriguing observations, as things currently stand, caffeine has no "real place in pharmacotherapy" (Werry, 1994:327). Caffeine probably offers little or no benefit in the treatment of canine hyperkinesis; however, to my knowledge, the potential value of caffeine for controlling hyperkinesis in dogs has not been clinically evaluated.

Essential fatty acids (EFAs) are necessary for healthy brain development and function. Children with EFA deficiencies, especially omega-3 fatty acids, may be more prone to exhibit learning difficulties and behavior problems associated with ADHD (Stevens et al., 1996). Supplementation with EFAs has been shown to alleviate ADHD-related behaviors and improve cognitive function in children. The value of EFA supplementation in dogs exhibiting hyperactivity, inattentiveness, and impulsivity has not been clinically evaluated, but given the apparent benefits of such supplementation in human psychiatry (see *Aggression and Diet* in Chapter 7), such investigation appears to be warranted.

Note: The foregoing information is provided for educational purposes only. If considering the use of medications to control or manage a behavior problem, readers should consult with a veterinarian familiar with the use of drugs for such purposes in order to obtain diagnostic criteria, specific dosages, and medical advice concerning potential adverse side effects and interactions with other drugs.

BEHAVIOR THERAPY

Hyperactive dogs exhibit several cognitive and behavioral characteristics that may impair their ability to organize behavioral output and effectively adjust. In addition to increased activity levels, hyperactive dogs are easily distracted, impulsive, and lack the ability to rapidly stop or inhibit motivated behavior. The sheer volume of searching and impulsive activity exhibited by such dogs can be daunting and extremely frustrating for dog owners. Since hyperactive dogs show a characteristic inability to respond to conditioned inhibitory signals, an excessive reliance on interactive punishment is common, often making matters worse. A hyperactive dog's inability to stay still for long appears to be a function of emotional impulsivity (seeking-system imbalance), driving the dog to seek drive-activating stimulation or intensify gratification. As a result, performing tasks requiring a delay of gratification or response inhibition places an onerous demand on such dogs. Instead of hesitating, appraising the situation, and selecting an optimal course of action (control module), hyperactive dogs appear to respond swept up by transient impulses in search of immediate gratification. In addition to emotional impulsivity, the behavior of such dogs appears to be dominated by insatiable modal searching routines operating under exploitative incentives. Many of these dogs exhibit a low-threshold orienting response, causing them to scan the environment rapidly and without lingering for long on any one source of stimulation.

Reinforcement and Extinction Peculiarities Associated with Hyperactivity

Sagvolden and colleagues (1998) have proposed that normoactive and hyperactive animals (spontaneously hypertensive rats) and ADHD children respond differently to reinforcement and extinction procedures. ADHD children appear to be averse to reinforcement delays, preferring the accumulation of small rewards delivered immediately to the receipt of larger rewards requiring them to wait. In contrast with hyperactive counterparts, normoactive children appear to prefer schedules of reinforcement in which rewards are gradually maximized and presented as large accumulated earnings. Also, the behavior-strengthening effects of delayed and immediate reinforcement significantly differ between normoactive and hyperactive animals and

children. In normoactive animals, not only are behaviors that directly result in reinforcement strengthened, but so are other responses leading up to the reward. More formally stated, a delay of reinforcement gradient is formed as a function of the time elapsing between the emission of a response and the delivery of reinforcement, such that behaviors occurring early in the sequence are strengthened but to a lesser extent than those occurring immediately before the reinforcing event (Figure 5.1). In the case of hyperactive animals, only those behaviors occurring in close proximity with the delivery of reinforcement are affected, gradually resulting in their exaggeration and predominance over behaviors occurring earlier in the sequence. After repeated trials, reinforcement causes hyperactive animals to differentiate from normoactive counterparts in interesting ways. For example, the behavior of normoactive animals tends to be more goal oriented and organized in comparison to the hyperactive animal's impulsive and massed response bursts primarily occurring just before reinforcement is anticipated to occur. These findings suggest that the

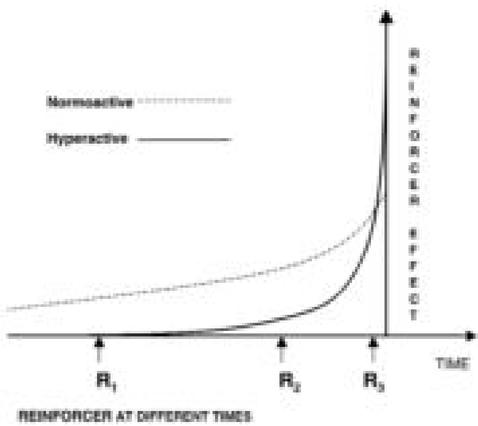

FIG. 5.1. Theoretical delay of reward gradient comparing hyperactive and normoactive animals. Hyperactive dogs appear to be affected by a number of learning impairments, including a delay of reinforcement deficiency that impedes their ability to produce goal-directed and organized output. Unlike normoactive counterparts, hyperactive dogs tend to concentrate impulsive behavioral efforts to occur immediately before the anticipated reward is delivered. After Sagvolden et al. (1998).

impulsivity associated with hyperactivity may be acquired as the result of the distinctive way hyperactive animals respond to reinforcement. In addition, hyperactive rats appear to respond differently to extinction procedures than do normoactive ones. Although hyperactive rats initially exhibit a reduction of behavior during signaled extinction trials, they rapidly resume responding and persist in doing so at high levels despite the absence of reinforcement. Hyperactive rats appear to recognize when reinforcement is no longer forthcoming, but are unable to maintain response inhibition during signaled extinction periods. Similarly hyperactive dogs exhibit intolerance for waiting and respond best to immediate reinforcement. During the training of such dogs, it is important that rewards be presented on a frequent basis rather than requiring them to wait too long or perform several responses for a deferred reward. Consistent with findings from experiments with hyperactive animals and children diagnosed with ADHD, extinction procedures (ignoring intrusive and impulsive behavior) are not usually very effective in the behavioral treatment of hyperactive dogs.

These various impairments of reinforcement and extinction processes impede a hyperactive dog's ability to adjust to changing circumstances, with the consequent breakdown of integrated behavior. Impulse control develops as the result of goal-directed behavior and inhibitory conditioning processes occurring naturally as organisms interact with the environment. Normally, dogs learn from an early age that certain behaviors are either dangerous or do not pay off, and consequently learn to stop exhibiting those actions—a process that is gradually internalized as impulse control. Dogs also learn that some behaviors alter the environment in ways that produce pleasurable or rewarding outcomes. Consequently, two general alterations occur during the process of behavioral adaptation: (1) response inhibition (impulse control) and (2) response excitation (goal-directed and integrated behavior). Adaptive behavior is motivated to avoid aversive events, on the one hand, and to optimize control over attractive ones, on the other. Practically speaking, socially acceptable behavior is acquired and

maintained by structuring the dog's activities in accordance with various contingencies of reward and punishment. Training procedures consist of attractive and aversive events presented in accordance with controlling signals (e.g., discriminative stimuli and conditioned reinforcers) in order to systematically shape behavior toward some behavioral objective. In the case of disruptive hyperactive behavior, the goal of behavior modification and training is to promote the development of a regulated and organized repertoire of cooperative behavior. Training activities serve to establish instrumental control modules and routines that are incompatible with disruptive impulsivity to enhance attention and impulse control, and to generally increase the dog's ability to effectively organize its behavioral output. A dog's ability to control impulsiveness involves at least four aspects: the ability to restrain a preferred response at the level of intention, to stop an action that has been initiated but not fully consummated, to continue an action despite environment interference, and the ability to delay a response (see Rubia et al., 1998). All of these aspects are addressed in the training of hyperactive dogs.

Reward-based Training and Play

The training of hyperactive dogs involves shaping instrumental control modules (e.g., sit, down, and stay) and improving attending and waiting behaviors. The strengthening of enhanced attention and impulse control is most practically and beneficially attained through highly structured and reward-based training efforts in combination with TO and response-blocking procedures. Such training should focus on developing a repertoire of compliant behaviors integrated into everyday activities. First establishing a set of highly consistent predictive control expectancies and then varying the type, size, frequency, and timing of attractive outcomes against this control expectancy standard helps to optimize reward-based training efforts by introducing positive prediction error (surprise) and a variety of beneficial dissonance effects. Not only does basic training induce a significant calming effect in most hyperactive dogs, it also provides owners with more constructive means for controlling impulsive and oppositional behavior. In addition to basic training and attention therapy, providing hyperactive dogs with contingent access to vigorous play activities can further enhance control efforts while providing overactive dogs with beneficial ways for obtaining high levels of quality stimulation and reward. Ball play can be structured so that the opportunity to chase the ball is made contingent on the dog waiting by standing, sitting, or lying down, thereby improving impulse control and reinforcing more cooperative behavior. Playful activities that involve jumping up, biting and tugging on toys, running about, and wrestling (in the case of friendly dogs) can be provided contingently as a reward following the performance of basic exercises. Also, repeatedly turning play on ("Okay") and off ("Enough" or "Out") appears to help overactive dogs to learn better self-control over playful social excesses and impulsive behavior.

Time-out, Response Prevention, and Overcorrection

The most common means used by dog owners to control hyperactive excesses are extinction and punishment. Efforts to extinguish hyperactive behavior by ignoring it are rarely successful, and the punitive measures often used by owners are inconsistent and ineffective, usually only serving to exacerbate the situation. Disruptive hyperactive behavior may be so pervasive and persistent that reward strategies may be thwarted, requiring complementary inhibitory training efforts aimed at restraining oppositional or intrusive excesses. The most successful programs of behavior therapy and training combine reward-based training, punitive procedures (e.g., exclusionary and nonexclusionary TO), and various response-blocking techniques. Keeping the dog on leash while in the house enhances the owner's ability to interrupt and redirect unwanted behavior, effectively apply TO procedures, and prevent many common excesses associated with hyperactivity.

In combination with TO and response blocking, overcorrection can be highly effective. The overcorrection procedure requires that the dog repeatedly perform a behavior

that is incompatible with hyperactivity [see *Negative Practice, Negative Training, and Overcorrection (Positive Practice) Techniques* in Volume 1, Chapter 8]. One overcorrection procedure requires that the dog perform a long-down stay (1 to 10 minutes) whenever it exhibits a loss of impulse control or target-intrusive excess. Initially, the dog is frequently rewarded with affection and food while staying in place, with the reward frequency gradually tapering off until it is delivered only at the end of the stay period. Massage can help encourage a dog to relax, especially if the dog needs to be manually restrained in the down position. Another overcorrection technique requires that the dog repeatedly perform a series of obedience exercises (e.g., sit, down, sit from the down, and stand). Each behavior is positively reinforced, and the full overcorrection cycle of exercises is slowly repeated 5 to 10 times in a row, as needed to restore attention and impulse control. Similarly, hyperactive dogs can be exposed to integrated compliance training, which requires dogs to sit, stay or wait, and make eye contact before engaging in various preferred everyday activities. For example, hyperactive dogs should be routinely required to sit, wait, and make eye contact before being let outdoors, before being let indoors, before receiving treats and meals, before going up or down stairs, before getting into the car, before being released to play, before being permitted on furniture, and before receiving affection and petting. The idea is to use everyday rewards as opportunities to enhance attention and impulse-control abilities.

By defining (and adjusting as necessary) a continuum of progressive compliance, owners are better able to direct behavioral change in an efficient and goal-directed way, minimizing negative interaction and reactive resistance—undesirable outcomes that are more likely to occur in cases where more difficult demands are made too hastily. The next important step in the process is to generalize learning to a broader range of situations that provide greater environmental and social stimulation of the dog. For example, once training is mastered in the home, it can be gradually transferred to other more uncontrolled situations. Enrolling the dog in an obedience class can be extremely useful at this point. To be most effective, all family members need to play an active and consistent role in the training process.

Posture-facilitated Relaxation Training

Few activities are more beneficial than posture-facilitated relaxation (PFR) training and massage for promoting calmness and composure in hyperactive dogs. The musculature of such dogs is often stiff with anticipation and readiness to act, especially in the case of dogs operating under the influence of heightened sympathetic arousal. Hyperactive dogs often reach a deep state of relaxation more rapidly than normoactive counterparts. The procedure incorporates nonthreatening prompting movements together with sustained massage toward the induction of a pronounced relaxation response. The postural prompting and restraint associated with PFR training appears to play an instrumental role in the relaxation process (see *Posture-facilitated Relaxation* in Chapter 6 and Appendix C). As the result of such handling, opponent tensing and releasing of muscles produces a progressive calming and enhanced receptivity to massage. The induction of relaxation by systematically tensing and releasing of muscle groups plays a prominent role in the treatment of human fear and anxiety disorders by systematic desensitization. Grandin (1992) has reported some relaxation benefits associated with sustained squeezing in the treatment of human autism and hyperactivity. In addition to postural restraint and manipulation, taction helps to support and promote relaxation. Gantt and colleagues (1966) and others following him have emphasized the pronounced effect that touch contact has on dogs via the parasympathetic branch of the autonomic nervous system (see *Taction and PFR* in Chapter 7). Touch lowers blood pressure, decreases heart and respiration rate, reduces stress-activated hypothalamic-pituitary-adrenocortical (HPA) axis activity, and generally appears to promote homeostatic equilibrium. The combination of 10 minutes of reward-based training and 20 minutes of vigorous play, followed by a 5-minute session of PFR training, is a positive prescription for

change in the case of many hyperactive dogs.

HYPERACTIVITY AND SOCIAL EXCESSES

Hyperactivity and intrusive behavior appear to develop in the context of unresolved competitive conflicts and tensions. These interactive sources of conflict usually revolve around situations in which the mutual control interests of dogs and owners converge upon and conflict over the access to everyday rewards. Under the influence of owner interference and ineffectual control efforts, a puppy's behavior may become progressively organized around competitive modal strategies fueled by the intermittent reinforcement of intrusive and oppositional behavior. Problematically, the relationship between the owner and dog gradually takes form around these points of conflict and tension. Instead of producing harmonious and cooperative interaction, competitive exchanges and transactions between the owner and dog generate a variety of undesirable emotional and behavioral outcomes. In the dog's case, its behavior may become progressively hyperactive, intrusive, and disruptive. The owner may interpret the dog's emergent competitive behavior as dominating and threatening social order, but, in fact, these dogs are more aptly described as dependent and incompetent subordinates in search of a leader. Furthermore, the greatest actual threat to social order in such cases is the owner's failure to assume an appropriate leadership role and help the dog learn more acceptable ways to gratify its needs. Operating under the delusion of a dominance challenge, the frustrated owner may reactively turn to ineffectual and inconsistent punitive efforts to control disruptive behavior. Punishment in such cases may only serve to further complicate interactive conflicts and tensions, amplify competitive arousal, and further differentiate the dog's incompetent efforts to gain control over everyday sources of comfort and safety (reward). Instead of finding a leader, the dog finds a punitive adversary impeding its ability to adjust and succeed. In addition to exaggerating undesirable active-submission behaviors (e.g., jumping up, barking, and begging), the chronic reliance on punishment may cause the hyperactive and intrusive dog to gradually lose its ability to truly submit and defer, but nonetheless refrain from openly competing with the owner. Instead, the dog may engage in a variety of socially flirtatious and ambiguous behaviors involving obnoxious submission and defiance, especially when interacting with the owner around contested boundaries and limits. The dog may become progressively demanding, clever, and evasive in the process of learning how to get around the owner's control efforts. Instead of learning how to defer and wait, under such circumstances, the intelligent dog learns to sneak and steal what it needs.

Dogs need a balance of dominance, leadership, and nurturance in order to form healthy social bonds with people and to develop well-adjusted behavior. In cases where social conflict is implicated as a potential factor underlying hyperactivity and intrusive excesses, efforts should be taken to promote a voluntary subordination strategy (see *Social Competition, Cooperation, Conflict, and Resentment* in Chapter 7) by means of reward-based training, play, and PFR training. Leadership is established by showing the dog how to succeed in its efforts to obtain reward and avoid punishment. The various points of disruptive social conflict and tension should be interpreted and explained to the owner in terms of potential sources of reward and opportunities for leadership and interactive growth. Rather than interfering with the dog's control efforts and needs, the goal of training is to show the dog how to get what it wants by following rules and cooperating with the owner's directives. Through cynopraxic training, the dog learns that the owner can help it to achieve control over its interests rather than represent an impediment standing in the way of them. Integrated compliance training (ICT) is used to attain these objectives. The ICT protocol integrates training activities with everyday sources of reward (e.g., food, play, affection, going outside, coming up on furniture, jumping up, and barking) in order to defuse and resolve interactive conflicts and tensions that have developed between the owner and the

dog around these activities. Reward-based ICT efforts improve owner control efforts, reduce social ambivilence (adverse anxiety and frustration), enhance affectionate bonding processes, promote interactive harmony and mutual appreciation, and restore trust and respect between the owner and the dog. As the interaction between the owner and the dog becomes more competent and cooperative, a spontaneous reduction in oppositional and intrusive behavior, adjunctive attention seeking, and hyperactivity naturally follows.

Conventional wisdom asserts that behavior maintained by intermittent reinforcement is more resistant to extinction than behavior maintained by continuous reinforcement. Intermittent reinforcement is a potent source of prediction error and dissonance. The process of reducing or omitting reinforcement (negative prediction error) for a variable number of times serves to set the stage for the occurrence of positive prediction error and reward when the reinforcer is again delivered. Many adjustment problems appear to be maintained by intermittent and inadvertent (bootleg) reinforcement, generally reducing the value of extinction as a behavior-control procedure (see *Extinction of Instrumental Learning* in Volume 1, Chapter 7). One way to address this problem is to first bring the target behavior under the control of continuous reinforcement before initiating the extinction procedure (Ducharme and Van Houten, 1994). Switching from intermittent to continuous reinforcement prior to extinction appears to reduce the baseline level of the inappropriate behavior while at the same time facilitating subsequent extinction efforts (Lerman et al., 1996). For example, in the case of jumping up, dogs can be rewarded each time they jump up until a noticeable flattening or decline in response frequency is observed (plateau), whereupon the behavior can be brought under stimulus control by rewarding only those jumping responses that occur in the presence of the jump-up signal ("Hup"). Jumping-up responses that occur off signal are ignored (extinguished) or blocked. The type, size, and frequency of attractive outcomes are varied to maximize surprise in association with jumping up on signal, thereby encouraging the dog to defer and wait for the signal giving it permission to jump up.

Jumping Up

Jumping up is among the most common behavioral complaints presented in association with hyperactivity. Often initially invited and permitted as an expression of affection, owners rapidly learn to regard this common greeting excess as a nuisance, particularly when large dogs persistently jump on unappreciative guests. Dogs that jump up represent a significant risk of injury to young children and elderly adults, who may be knocked down when bumped into or jumped on. Owners of such dogs are often forced to isolate their rowdy dogs when guests arrive—a procedure that may eventually generate more problems and do nothing to improve the dog's intrusive greeting behavior.

Early training consisting of sit-stay and other exercises promoting impulse control when the puppy seeks attention or other rewards helps to encourage more acceptable and organized social behavior. From an early age, jumping up and other intrusive social excesses should be limited, redirected, and brought under stimulus control. During greetings, the owner should crouch down or sit on the floor and allow the puppy to nuzzle and press in closely, but not permit it to climb up on the lap without an invitation. While sitting on the floor with the puppy, the owner can practice various basic obedience exercises (sit, down, and stand) using petting and treats to reward cooperative behavior prompted by voice and hand signals. Providing the puppy with an occasional opportunity to play tug and fetch with a ball or soft toy can help to redirect excessive energy into play activities and further encourage cooperative behavior. When the puppy is greeted from a standing position, stepping on the leash and diverting its attention toward the floor by dropping treats or tossing it a soft toy can help to prevent jumping up while simultaneously encouraging more desirable behavior (see below). Training the puppy to jump up and off again on cue can be a useful way to establish better control over the behavior. If

the puppy becomes overly aroused and excited, repeated brief TOs (30 seconds) can exert a pronounced de-arousing effect. Consistent discouragement of off-cue jumping up by turning away or by applying brief TOs serves to gradually weaken the puppy's enthusiasm for the habit. In general, the best results are obtained by shaping alternative behavior with reward and play rather than focusing excessively on suppressing undesirable behavior. Keeping in mind the dead-dog rule (see *Dead-dog Rule* in Volume 2, Chapter 2), training objectives involving jumping up should be organized in affirmative terms, that is, shaping alternative behaviors incompatible with jumping up rather than training the puppy not to jump up—dead dogs do not jump up.

Overly excitable and active puppies often benefit from PFR training. The postural control and taction techniques of PFR training are described in Appendix C. An abbreviated cycle of PFR training is initiated by taking the puppy by the collar and briefly massaging the jaw muscles, followed by the stand control, whereupon a focused and rhythmic massage is delivered on the neck and shoulder muscles. The massage should continue for 20 to 30 seconds before prompting the puppy to sit by gently squeezing just in front of the hip bones or by pressing forward behind the knees and guiding the puppy into the sit position. With the puppy sitting, the massage continues along its neck, spine, and lumbar areas. Next, the puppy's right leg is lifted up and forward from the elbow while it is gently and steadily lowered to the floor. The massage is continued in a calming and soothing manner. Lastly, the puppy is rolled over onto its side. Rubbing the jaw and temporal muscles can help to strengthen the relaxation response. Next, massage is directed toward the earflap, various muscled parts of the body, and the feet. As the puppy relaxes, the owner can present an odor (e.g., orange or lemon-orange mix) paired with the growing relaxation response. The puppy is released with an "Okay" and soft clap.

Controlling jumping up through extinction alone—that is, ignoring the dog or turning away from it—is not usually very effective. As a component of the greeting ritual, jumping up appears to be intrinsically reinforcing for dogs to perform. Also, given the adverse effects of periodic bootleg reinforcement and the impaired ability of hyperactive dogs to respond to extinction procedures makes procedures relying on extinction relatively ineffective for the control of hyperactive greeting excesses. The control difficulties arising in association with the intrinsic reward value of jumping up and intermittent reinforcement can remedied in four preferred ways:

1. Put the behavior on a continuous schedule of reinforcement and then bring it under stimulus control.
2. Block or correct jumping up whenever it occurs.
3. Teach the dog an alternative greeting behavior that pays off more than jumping up does.
4. Allow the dog to jump up as a reward for not jumping.

Training procedures often include all four methods of control applied in varying proportions as required by the situation and the needs of the dog.

Building improved attention and impulse control during greetings is facilitated by focusing training efforts on orienting and attending behaviors. The first step is to train the dog to reliably orient toward the trainer in response to hearing its name or the sound of a squeaker. If the dog fails to orient when its name is called, the squeaker or other sources of attention-grabbing stimulation (e.g., repeated smooch sounds) are used to evoke the orienting response. As soon as the dog turns its head, a click or "Good" bridge is delivered, followed by a food reward as the dog approaches the trainer. Next, the dog is trained to sit-front, look up, and hold eye contact with the trainer for variable periods (0.5 to 2 seconds) before the bridging signal and reward are delivered. After the food reward is delivered, the dog should remain in the sit position and wait to be released with an "Okay," whereupon the orienting, sit-front, and attending response are repeated. While the dog is waiting to be released, food rewards are delivered periodically contingent

on the dog looking up and making brief eye contact with the trainer. As the dog becomes steady in its ability to wait, a stay component can be added with the trainer maintaining eye contact as he or she steps back away from the dog. Numerous variations and elements of distraction and difficulty can be introduced to temper attention and impulse-control abilities (see Appendix A and Figure B.1A in Appendix B). Providing such training around the doorway establishes a useful platform for other reward-based training procedures used to control greeting excesses and other problems associated with greeting behavior.

Establishing control over excessive jumping behavior is facilitated by training dogs to jump up ("Hup"), to get off ("Off"), and to stay off ("Do you want this!") on cue. Dogs readily learn to jump up on signal after the behavior is brought under the influence of continuous reinforcement. Stimulus control is established by differentially reinforcing jumping responses that occur in the presence of the "Hup" signal and ignoring, blocking, or punishing (TO) jumping responses that occur in the absence of the signal. Off-cue jumping is associated with the vocal signal "Off," together with appropriate inhibitory prompts and rewards once the dog gets down. Impulse control associated with jumping up is significantly improved by using a challenge, especially at times when a dog is most likely to jump up off cue. The challenge serves to *dare* the dog to jump up, but without actually causing it to do so, whereupon the dog is rewarded for inhibiting the jumping-up response. The challenge consists of a prompt (e.g., slapping the legs or waist) that tempts the dog to jump up, together with a vocal signal delivered in an assertive tone of voice ("Do you want this!") belying the apparent invitation and causing the dog to hesitate. The dog's momentary hesitation is bridged and rewarded. This preemptive control procedure can be used to anticipate jumping up and promote a more reward-based approach to the problem. For example, when jumping up is highly probable, the owner can take the initiative by challenging the dog with the thigh or waist slap while saying "Do you want this!" Most dogs rapidly learn to hesitate in the presence of the challenge-dare, whereupon they are appropriately rewarded with affection, a treat, or an opportunity to jump up on signal. The challenge-dare is combined with other integrated compliance-training activities (waiting to go through doorways or to climb up and down stairs, sitting and staying for treats, waiting for permission to jump on furniture, and so forth). Such training is essential in cases where a habit of jumping up has been strongly established in a dog's greeting repertoire.

Staging actual greeting encounters with guests is a necessary part of retraining a problem jumper, but the first step is to train the jumper not to jump up on the owner during greetings. Most control efforts should be carried out with the dog on a leash. However, if the dog is off leash and jumps up, the owner should simply shout "Off!" and turn sharply away, thereby sloughing the dog off. Another method involves taking one or two steps backward and then stepping aside to throw the jumping dog off balance with a body block or sideways shove. Grasping the front paws momentarily and releasing them only after the dog struggles to break free can be effective (Mathews, 1983), but grasping the paws or legs should be done only in the case of dogs that are unlikely to mouth or bite as the result of such restraint. Alternatively, the legs can be grasped and the dog walked backward before shoving it off to the side with a reprimand "Off" delivered just as the paws are released. In any case, the dog should be immediately put on leash, whereupon directive control, challenges, response blocking, and TO procedures can be carried out in conjunction with the reward-based training of alternative behavior.

When greeting visitors, the dog should be kept on leash, giving the owner better control and the ability to apply response prevention and blocking (e.g., stepping on the leash) and TO procedures. Before opening the door, a treat (e.g., a small biscuit) is tossed, making a sharp tapping sound as it strikes the base of the door. As the dog takes the treat, the owner steps on the leash. Additional treats are dropped to the floor as the guest enters the house. Presenting noncontingent rewards during greetings generally has a calming effect on socially excitable dogs, perhaps by

evoking incompatible appetitive incentives that compete with social motivations driving greeting excesses. Treats may also perform an establishing operation function, thereby causing the dog to offer behavior that has been rewarded with food in the past. After receiving the noncontingent treats, the food can be withheld to reinforce sitting and waiting or presented according to a differential reinforcement of other behavior (DRO) schedule (see *Differential Reinforcement of Other Behavior* in Volume 1, Chapter 7). When using the DRO schedule, a bridged reward is delivered after a brief period (2 to 10 seconds initially), provided that the dog does not jump up. After establishing a control expectancy standard, the length of the DRO interval and the rewards given to the dog can be varied to produce better-than-expected and worse-than-expected outcomes (e.g., shorter DRO intervals or alterations of reward type and size), thereby mobilizing potent prediction-dissonance effects. Over time, the DRO schedule results in the strengthening of a varied spectrum of social behaviors that happen to occur coincidentally with the delivery of the bridge and reward. In general, presenting rewards in accordance with a DRO schedule is highly effective for managing and controlling the intrusive social excesses of highly excitable and active dogs at greetings, thereby reducing the need for punitive measures. Once intrusive greeting excesses are reduced via DRO and TO, a behavior incompatible with jumping up can be shaped (e.g., sitting or standing quietly) and reinforced according to a DRI schedule of reinforcement (see *Differential Reinforcement of Incompatible Behavior* in Volume 1, Chapter 7). Finally, because the doorbell often elicits intense conditioned preparatory arousal in association with greetings, it may be necessary to countercondition a new set of anticipatory emotions in response to the ringing of the doorbell. An electronic doorbell can be installed that allows the owner to ring the bell from inside the house. In addition to providing constructive counterconditioning effects, such an arrangement helps to shape and practice the various modules and routines needed to control the dog effectively during actual greetings.

For dogs that actively resist such training efforts and continue to jump up, an additional assertion of control may be necessary. With the dog on leash, it is caught midair and reprimanded "Off" and shoved to the side. The procedure is immediately followed by a "Do you want this" challenge and dare, and the dog is rewarded if it refrains from jumping up again. If, instead, the dog jumps up again, the reprimand "Enough!" and a directive leash prompt are delivered just as the dog jumps up, whereupon it is briskly removed to TO. During greetings, the dog is most effectively timed-out on the other side of the same door that the guest used to enter the house, with the leash pinched in the doorjamb. During the TO, the dog should be given enough slack to stand and sit comfortably but not be able to move around or lie down. After a brief TO (approximately 30 seconds), the dog is brought back inside and permitted to have close contact with the guest. If it jumps or becomes overly excited, the TO procedure is repeated, as necessary. With each TO, a significant decrease in arousal and jumping should be observed, thereby complementing DRO training efforts. If the dog jumps during DRO training, the response can be blocked by stepping on the leash or punished by additional TOs. Once the dog stops jumping, it is challenged (as described previously) and rewarded when it hesitates and inhibits the jumping response. After a few repetitions of TO, most dogs not only learn to inhibit the jumping response, they also learn to move away from the doorway as guests enter the house, perhaps in an effort to reduce the risk of being put outside. This method can be surprisingly effective with even the most recalcitrant jumpers. To further improve greeting behavior, the dog should learn to withdraw from the door by backing up as it is opened. This behavior can be mastered by practicing it before walks or whenever else the door is opened. If a treat is consistently tossed back from the door as it is opened, gradually the hand movement will become a signal controlling the backing or turning-away response. If necessary, the dog is directed away from the door with directive prompts. Before exiting the house, the dog should wait for a release signal to move

through the doorway. Training overactive and impulsive dogs to approach and to go through doors without pulling is an indispensable aspect of establishing control over greeting excesses. Dogs that charge through the door can be discouraged from the habit by bringing them to a dead halt and then closing the door on the leash and leaving them outside for 30 seconds, before bringing them back inside and repeating the procedure again.

Especially difficult dogs can be conditioned to stay within the area of a rug located near the entryway. Training the dog to go to the rug and stay on it should be accomplished to a high degree of reliability before it is used to control a dog around guests. The safe rug should be large enough for the dog to turn around without stepping off. During greetings, the dog should be kept under close supervision and restrained by leash and collar or halter in order to block or correct jumping attempts, whereupon the guest initiates a brief nonexclusionary TO by backing away from the dog. At the conclusion of the TO period, the guest approaches the dog again and continues to reward it with food and affectionate attention, so long as it does not become overly intrusive or jump up. Once the dog calms down, it can be released from the confinement area and permitted to move about more freely with the guest. If the dog jumps up, appropriate leash and physical prompts and exclusionary TOs are applied as needed to discourage the behavior. Throughout the process, frequent rewards are delivered on a DRO or DRI schedule in order to encourage and support more acceptable greeting behavior. In addition to performing sit-stay and down-stay training on the rug, PFR training can be performed on it as well, thereby developing a number of convergent associations conducive to impulse control and relaxation.

Once a dog has mastered the basic pattern of greeting without jumping, a variety of startle tools may be used to further strengthen the inhibition against jumping up. Most dogs can learn not to jump up without resorting to startle, but some may need such treatment to become fully compliant and reliable. For some dogs, tossing keys on the floor can be convenient and sufficient for such purposes, but other dogs may require a more impressive startle event. For example, the startling rattle produced by a seven- or 30-penny shaker can tossed to the floor can be highly effective. Ideally, the shaker can is tossed without the dog observing the action. As a result, merely tapping on the shaker can will often produce a potent inhibitory effect over the impulse to jump up. In the case of dogs possessing a high startle threshold, a brief burst of compressed air dispensed by a modified carbon-dioxide pump (with or without odorant) can produce a potent startle response, but the device needs to be used carefully to avoid overstimulating the dog (see *Modified Compressed-air Pump* in Chapter 2 for precautions). The delivery of compressed air should be concealed from the dog by applying it from behind or sprayed lightly under the jaw toward the ground: it should never be pointed and sprayed at the dog. A dilute odor sprayed from the nozzle of the pump will linger in the air and provide an olfactory reminder to the dog not to jump up again. As the result of olfactory conditioning, a squeaker bulb (without squeaking element) containing the odor can be subsequently used to deter jumping up. Presenting the conditioned odor appears to make other startle devices more effective via a startle-potentiating effect. Once sensitized to the hissing sound of the pump, a similar sound produced by blowing air between the tongue and front teeth may function as an effective warning. The use of devices producing extreme auditory startle or that risk damaging the ears of the dog or people standing nearby (e.g., a compressed nautical horn) should be avoided. Squirting the dog in the face with a spray bottle or squirt gun is not recommended, since it appears to promote undesirable avoidance behavior in many dogs. In some cases, the delivery of a dilute odor (e.g., orange or lemon-orange mix) from a working squeaker bulb can have a potent diversionary effect that is frequently sufficient to reduce jumping without needing to resort to more startling procedures. The presentation of the odor together with the squeaker sound appears to produce a strong momentary disrupting effect, but without generating significant startle, making the technique useful in the case of emotionally sensitive dogs.

In rare and extreme cases of persistent jumping that is not otherwise controllable, in cases where jumping-up behavior represents a significant threat of injury (e.g., to elderly dog owners), or in cases involving persons unable to perform the necessary leash controls and prompts, TO procedures, and so forth, the use of a remote electronic procedure may be warranted. Both chemical (citronella) and electrical devices are highly effective deterrents, but each requires proper introduction. Electrical collars require preliminary training that allows the dog to learn how to control the electrical stimulus (e-stimulus) by way of various exercises and response-enhancement procedures (see *Remote Electronic Training* in Chapter 10). Electronic training procedures should be used only after a dog has had sufficient instruction with reward-based procedures to understand what is expected. Electrical stimulation (ES) is primarily used to train a dog to back away from the door and remain away at some distance as a guest enters the house. Remote electrical training can be used to support training efforts to keep the dog on the safe rug during greetings. Throughout the process, the dog should receive frequent rewards in response to more desirable and cooperative greeting behavior. Although low-level and medium-level electrical stimulation (LLES and MLES) are unlikely to elicit aggression in a normal and friendly dog, nonetheless ES should not be delivered while a dog is in the act of jumping up or while it is in direct contact with a visitor. The close control of social excesses should be performed with a leash and collar or halter. An experienced and skilled trainer familiar with the risks and benefits of ES should supervise such training activity. Highly aversive ES in such circumstances is unwarranted and could result in undesirable fear, conflict, or the elicitation of pain-elicited aggression in predisposed dogs. Electronic and startle-producing devices should be used with the goal of providing a window of opportunity for additional reward-based training.

Barking

The causes underlying barking problems are varied, requiring that provoking situations, controlling antecedent variables (establishing operations), and contingencies of reinforcement be carefully identified and assessed. Many barking problems appear to be motivated by attention-seeking incentives, inappropriate or frustrated communication efforts, and a history of inadvertent reinforcement. Barking and other canine vocalizations are strongly influenced by heredity and perform a variety of species-typical communication functions (see *Barking, Motor Displays, and Autonomic Arousal* in Chapter 8). Barking activity is clearly increased by a history of positive reinforcement (Salzinger and Waller, 1962) and reduced by punishment. Many barking dogs have learned to place the gratification of their needs on demand: they may bark to go outside and to come back in, to demand food and its timely delivery, to badger the owner into playing with them, to wake the owner up in the morning or in the middle of the night (should they become lonely or bored), or to divert the owner's attention away from guests during greetings. An important aspect of training dogs not to bark is to remove the incentives to bark, that is, discontinuing the reinforcing consequences maintaining the barking behavior. Owners should discourage inappropriate barking and train their dogs to show more acceptable behaviors as a means to get what they want. Many barking problems can be managed or prevented by taking care to provide the dog with adequate daily exercise, training, and play. Defusing or redirecting heightened arousal into other activities (e.g., tossing the dog a soft toy or ball) or leaving it with a special toy or chew item when it is confined can significantly curb excessive barking. Many hyperactive dogs are insatiable enthusiasts for ball play. As the result of structured tug-and-fetch games, the ball can be made into a potent source of reward and diversion. Many hyperactive dogs prefer to have a ball in their mouth rather than bark, unless they happen to learn how to hold a ball and bark at the same time (not an uncommon canine skill). Aside from humor, the consolation in such cases is that at least the barking is muffled.

In active and excitable dogs, excessive barking may be evoked by environmental triggers having innate or species-typical signif-

icance, such as territorial intrusion, sudden movements, auditory startle, or the presence of animals beyond their reach (e.g., seeing a squirrel run across the lawn from a window). Such barking may occur independently of the owner's presence or absence. In many cases, barking appears to obtain reward from the effects it has on the object setting the occasion for the barking response. For example, barking at passersby or dogs roaming the neighborhood may be coincidentally reinforced when the target stimulus moves away—a change that reliably occurs when the dog barks, even though the action does not actually depend on the dog's barking response. Situations evocative of approach-avoidance conflict or frustration (e.g., fence lines shared with another dog) may generate high levels of barking. Finally, in situations involving more than one resident dog, barking excesses may develop as the result of social facilitation (see *Social Facilitation* in Volume 1, Chapter 7).

As in the case of jumping up, it is often useful to begin the training process by introducing attention and impulse-control training, thereby developing in advance strong orienting and attending responses, viable bridges (click and "Good" conditioning), a sit-stay module, and waiting behavior. Controlling excessive barking often involves bringing the nuisance barking behavior under stimulus control, that is, training the dog to bark on command (e.g., "Speak"). At first glance, such a training recommendation may seem odd to the average dog owner; nevertheless, it is a very effective means to help reduce unwanted barking. As a preliminary to stimulus-control training, barking is briefly put on a continuous schedule of reinforcement by clicking and rewarding barking behavior whenever it occurs. The instrumental barking module is then brought under the control of a vocal signal by saying "Speak" just as or before the dog barks, followed by the bridging signal and a food reward. Initially, the dog will bark both on cue and off cue, but as it learns that rewards are presented only when barking occurs in the presence of the vocal signal, barking off cue will gradually weaken as the result of extinction. In some cases, DRO training can be combined with stimulus-control efforts to help reduce excessive barking off cue. At the end of the DRO period, the bridge "Good" or a click is delivered with a food reward, provided that the dog has not barked. Alternatively, the dog can be prompted to bark on cue at the end of the DRO period. If the dog barks during the DRO period, the vocal signal "Enough" is delivered and the DRO period is reset or the dog is briefly timed-out. By combining DRO and stimulus-control training, the dog gradually learns that both waiting without barking and barking on cue results in positive reinforcement.

Exclusionary and nonexclusionary time-outs (TOs) can be useful when applied in the context of DRO and stimulus-control procedures. TO exerts the dual effects of reducing arousal and causing a dog to learn that barking leads to the loss of rewards and attention, whereas refraining from barking results in release from TO and their reinstatement. Barking that continues in TO can be gradually extinguished by ignoring it or by opening the door slightly and snatching upward on the leash with the reprimand "Enough." The TO should typically last 30 seconds, although longer TOs may be necessary for some dogs, but rarely more than 1 minute. After the 30-second TO, provided that the dog has not barked for at least 10 seconds, it is released with the vocal signal "Quiet" and returned to the evoking situation. For TO to be optimally effective, the training situation should be reward dense, making restraint and isolation unfavorable in comparison. If the training environment is excessively punitive, TO may not work as well or perhaps not work at all. In effect, under aversive circumstances, involving a high level of punishment and too little reward, TO from the situation may be experienced in terms of relief rather than punishment (see *How to Use Time-out* in Volume 1, Chapter 8).

While a dog is tethered, kept behind a gate, or crated, leaving the dog with a highly valued chew item or tossing it noncontingent rewards in accordance with a DRO procedure can often help to reduce excessive barking. In some cases, barking can be interrupted by

evoking an orienting response with the sound of a squeaker or whistle that has been strongly conditioned as orienting stimulus in the context of basic training activities. The cessation of barking is followed by a bridge ("Good" or click) and food reward, thereby linking the expectation of reward with orienting and the discontinuation of barking. Gradually, the vocal signal "Quiet" is paired with the orienting and bridging sequence. Although such techniques can help to frame, process, and modulate barking activity, the control attained by such means may not be reliable or durable. In most cases involving excessive and persistent barking, effective control requires an element of deterrence. The startle produced by a seven- or 30-penny shaker can is often sufficient to generate the necessary inhibitory effect. The shaker can is tossed in the direction of the barking dog so that it lands close enough to evoke a startle response, but not so close that it risks hitting the dog. Ideally, the dog should not see the trainer throw the can. After two or three tosses, the dog may show an inhibitory response to a brief rattle of the can alone. An alternative method involves arranging a drop can to fall nearby on the floor from the vantage of a remote location. The drop can is set up by tying a length of dental floss to the ring of a soda can and then passing the line through a small eyehook fastened to the ceiling. The line should be long enough to allow the owner to move away, even to a remote part of the house, as needed. Initially, the can is dropped onto the floor by releasing the line, whereupon it is hoisted up to the ceiling again by pulling the dental floss. After two or three sensitizing trials in which the can is dropped, a brief shake or slight movement of the suspended can is frequently enough stimulation to interrupt barking. The owner should periodically return to the confined dog to reward it with affection, food, and release, so long as it remains quiet during the period of confinement.

Barking problems that are under the influence of specific eliciting stimuli can be managed by altering the environment (stimulus-change procedure) or counterconditioning. By arranging the environment so that provocative stimulation is prevented from reaching the dog (e.g., keeping windows closed and blinds shut that face on the street), the amount of daily barking can be substantially reduced. If the barking problem primarily occurs outdoors, bringing the dog indoors when the provoking stimulus is present also helps to reduce frequency and duration of barking episodes. Bringing the dog inside at such times may function as a TO event, thereby potentially helping to reduce future barking activity. In situations where environmental conditions cannot be changed, bark-provoking stimulation may be responsive to counterconditioning efforts. Counterconditioning is performed by pairing bark-eliciting stimuli with food or other sources of incompatible stimulation, thereby producing new associations and raising the bark threshold. For example, ringing the doorbell and immediately throwing a piece of food toward the door can gradually help to reduce excessive barking associated with greetings. The counterconditioning effect is augmented by repeated trials in which the size and type of the food treat are varied from trial to trial. Counterconditioning can be combined with a variety of instrumental training techniques, including DRO, stimulus control, and shaping procedures, whereby more appropriate behavior is strengthened and brought under control with positive reinforcement.

Barking excesses that occur outdoors or when the owner is not present pose significant challenges. Dogs that bark when outdoors should be trained to orient to a whistle and come when called (see *Recall Training* in Chapter 1), whereupon they are released and diverted into some other activity (e.g., ball play). Barking that takes place while the dog is alone is most frequently treated with bark-activated deterrents (see below). However, an automated application of the orienting and DRO procedures previously described might be useful in some cases of barking nuisances occurring in the owner's absence. A signaling and feeding device could be programmed to deliver an alerting stimulus whenever the dog barks, followed by a bridge and a small predictable reward when the dog stops barking in the presence of the signal. The device could

also be programmed to deliver a better and varied reward in accordance with a variable DRO schedule, with the bridge and food reward automatically occurring after some period of time, provided that the dog does not bark. After a number of successful DRO trials, indicating that the barking episode is over, the program could automatically reset. In addition to reward-based procedures, remote and bark-activated punishment and avoidance training can be useful (see *Electrical Stimulation and Excessive Barking* in Chapter 9). Although both bark-activated citronella and electronic collars can be effectively used to suppress barking excesses (Juarbe-Diaz and Houpt, 1996), citronella-type collars appear to be more prone to habituation effects, a factor that may limit their usefulness in situations involving repeated bark-provoking stimulation (Wells, 2001). Barking excesses associated with fear, aggression, and separation distress need to be appropriately assessed and addressed with suitable behavior therapy procedures, with remote or behavior-activated devices being used cautiously in such cases, if at all.

Excessive Attention-seeking, Begging, and Demanding Behavior

The causes of excessive attention-seeking behavior are varied, and each case requires individual assessment and evaluation before deciding on a course of treatment. Attention-seeking excesses may stem from exercise deficits, excessive confinement, social deprivation, interactive conflict and adjunctive influences, inappropriate social stimulation, or inadvertent reinforcement. A close phenomenological relationship appears to exist between attention-seeking and active-submission behavior (see *Attention Seeking* and *Adjunctive Generation of Hyperactivity* in Volume 2, Chapter 5). Many dogs that exhibit attention-seeking and intrusive excesses are often prevented from sleeping in the company of family members—a potentially significant etiological factor. Simply allowing the dog to sleep in a bedroom, providing it with more exercise, and developing a daily play and training routine often results in a rapid reduction of inappropriate attention-seeking behavior. Many overactive and excitable dogs exhibit impaired abilities to exert inhibitory control over stimulation-seeking impulses. Seeking behavior in such dogs may be dysfunctional, operating independently of normal inhibitory regulation, consummatory objectives, and reward gratification. Instead of being satisfied with the acquisition of the reward object and stopping, such dogs repeatedly entrain the seeking sequence without appearing to obtain gratification. Although punishment may momentarily blunt the seeking excesses exhibited by such dogs, the punished behavior often rapidly recovers or actually increases over time. Attempting to directly punish or extinguish modal activity without providing adequate alternative outlets is highly problematic (see *Autonomic Arousal, Drive, and Action Modes* in Chapter 10). Although control modules and routines associated with modal seeking (i.e., searching for drive-activating stimulation) can be extinguished, the modal-seeking propensity itself is highly resilient and relatively immune to the consequent effects of risk and loss. The mismanagement of normal attention-seeking and proximity-seeking behavior with positive and negative punishment may produce significant social conflict (affection-fear) and exaggerated active-submission behavior in the dog. A natural outlet for attention-seeking excesses is provided by play, especially play activities consisting of a balance of competitive and cooperative components (e.g., tug and fetch). Play integrates the active-submission aspect of attention seeking and gives it purposeful direction and function, helps to reduce social conflict, and provides an active modality for supporting basic training activities.

Attention seeking and begging behavior appear to be governed by a shared set of stimulation-seeking incentives. Like distractions, which really amount to environmental reinforcers not yet under the trainer's control, begging and demanding behavior reflect motivational states not adequately directed toward the enhancement of cynopraxic goals. Just as one may introduce and use attractive environmental stimuli (distractions) as contingent reinforcers to support training objec-

tives, begging and demanding behavior point to appetitive and social rewards not yet in the service of more cooperative behavior. From this perspective, attention seeking and begging (active-submission behaviors) are nuisances only to the extent that they have not yet been constructively redirected into more acceptable outlets. Just as environmental distractions represent a source of untapped reward for future training efforts, socially intrusive behaviors represent untapped opportunities for reward-based training activities. Training gives active submission (that is, attention seeking and begging) leadership and direction via nurturance. Many hyperactive dogs are simply *seeking and begging* for human leadership. Dogs of this nature are typically highly responsive to play-based and reward-based training efforts. When combined with appropriate limit setting and directive training efforts, play and reward training can be highly successful and should be earnestly encouraged in such cases.

Dogs appear to possess an innate tendency for begging, species-typical behavior that may have aided their survival as they became dependent on humans for food. As a result, begging is highly prepared and rapidly conditioned. By occasionally giving a dog food from the table, it may gradually learn to beg and subsequently develop various other pestering behaviors in other situations. As a nuisance, begging is a modal strategy that develops under the influence of a variable duration (VD) schedule of intermittent reinforcement and an element of punishment. A VD schedule provides reinforcement after the target behavior has occurred continuously for a variable length of time. VD schedules promote hopeful persistence via positive and negative prediction errors. Begging commonly produces two sources of significant positive prediction error: sooner than expected and better than expected outcomes. Demanding behavior operates under the influence of a similar prediction dissonance, but usually without a significant history of punishment. Hope, as a concomitant emotion associated with VD schedules, appears to be an outcome or function of a dynamic history of surprise (success) and disappointment (failure) occurring as the result of begging (see *Hope, Disappointment, and Other Emotions Associated with Learning* in Volume 1, Chapter 7). Hope facilitates the continuation of behavior in the face of suboptimal reinforcement conditions and punitive contingencies, with the expectation that the conditions of reinforcement will eventually change, as they have in the past. Under the influence of hope, frustration and fear are restrained, perhaps explaining the resistance of begging behavior to extinction and punishment efforts. Introducing an alternative modal strategy is the best way to control excessive begging. Such training usually involves a strong component of integrated compliance training, whereby the dog learns to earn attention and food and other everyday rewards by means of deferring, waiting, and cooperating. Instead of allowing the dog to get attention and food as the result of begging, the dog is trained to leave the situation, lie down, and stay (see *Go-lie-down* in Chapter 1). After a variable period of time, the dog is rewarded with food, affection, or release from the down-stay. During the early stages of training the go-lie-down routine, the dog is often put on an active-control line to facilitate the moving-away response and staying at a distance. The active-control line allows the owner to direct the dog away from the table without needing to get up—a feature that is particularly useful at dinnertime. To help prevent begging problems, dogs should not be fed from the table or other locations associated with food preparation.

NUISANCE OR GEM IN THE ROUGH

Dogs that exhibit an intense and persistent interest in social contact, appetitive and social rewards, and play activities, such as retrieving games and finding hidden objects, are often gems in the rough waiting to be developed. These highly active, sociable, and curious sanguine extroverts are in an almost constant state of readiness to work and play, which really amount to the same thing for them. Although tending toward excessive and impulsive behavior, such dogs are able to learn self-control and to behave in cooperative ways, provided that such training exploits

their drive to play and their exaggerated predilection for social and appetitive stimulation. The athletic drive and energy, playfulness, and *obsessive* single-mindedness of such dogs are often misinterpreted and mismanaged. As a result, many of these dogs remain gems in the rough or become gems lost to neglect or abuse because of mishandling or inappropriate training or punishment efforts. To succeed with such dogs, their behavioral potential needs to be actualized rather then suppressed, while at the same time shaping social behavior and skills compatible with domestic expectations.

Dogs of this sort are essentially normal, and there are no drugs or behavioral protocols that can transmute this sort of living gold into a baser substance without simultaneously destroying it. For dogs born to leap at life with passion, being trapped in a home with little appreciation or understanding of such a dog's capabilities and needs is simply a tragic state of affairs having significant welfare implications. From the perspective of many dog owners, however, the behavior of such dogs is an unbearable nuisance that is frequently treated in the worst possible ways. As a result, such dogs may develop a variety of secondary behavior problems that further complicate things, making their lives even more untenable and miserable. Owners living with these spirited sanguine-type dogs must truly accept the challenges associated with their training and exhibit a sincere appreciation of the extraordinary potential that such dogs represent; otherwise, hard decisions might need to be made. In situations in which an owner is unwilling to provide the sort of conscientious training and nurturance required to socialize and train such a dog properly, serious consideration should be given to counseling the owner to rehome the dog.

Neurobiology and Development of Aggression

PART 1: EVOLUTION AND NEUROBIOLOGY

Competition and aggression are virtually universal among highly evolved social animals.

The wide phylogenetic distribution and prominence of competition and aggression among social animals attests to their adaptive value. Although competition and aggression are of tremendous value for enhancing reproductive fitness and survival, excessive competition and aggression are risky and waste energy. Consequently, animals have evolved various means for regulating agonistic interaction in order to maximize benefits and minimize costs.

DOMINANCE AND THE REGULATION OF AGGRESSION

Of particular importance is the evolution of communication systems. Dogs have evolved a wide variety of social signals, displays, and rituals involving every sensory modality in order to exchange information and communicate (see *Communication and the Regulation of Social Behavior*, Volume 1, Chapter 10). An important function of social communication is to limit competition and prevent overt aggression. Various strategies have evolved to regulate aggressive tensions arising between individuals belonging to the same group as well as reducing competition between groups living in the same general area. Competition between individuals belonging to the same social group is regulated by the formation of hierarchically organized dominant and subordinate relations based on outcomes resulting from past competitive exchanges and contests. As a result of accumulated competitive successes or failures, group members take on various dominant or subordinate roles, consisting of attitudes and social behaviors consistent with their social rank. Social rank is advertised by the exchange and observance of social rituals consisting of threat and appeasement displays, the formation and exercise of stabilizing social alliances, and numerous other complex social customs (e.g., greeting and play behaviors) (Figure 6.1). An important function of threat and appeasement displays is to make competitive interaction more predictable and less socially disruptive and violent, thereby setting the framework for more cooperative interaction based on mutual tolerance and affiliative partnering. In well-organized and friendly groups competition is redirected into cooperative ventures serving the mutual interests of both dominant and subordinate group members. However, failure to observe the rules of dominance and priority (e.g., reproductive rights) may prompt pun-

FIG. 6.1. Wolves exchange a variety of threat and appeasement displays in the process of establishing and maintaining a dominance hierarchy. Alliances between pack members are formed to stabilize the status structure and to promote peaceful and cooperative member relations. The display of direct eye contact and other gross and subtle expressions of rank causes a subordinate to avert eye contact, lower ears, and display an appeasement lick—behaviors that are also exhibited by dogs in response to assertions of social dominance. ishment in the form of strong aggressive threats or overt attacks.

Coevolution, Play, Communication, and Aggression

The concepts of social dominance and territorial defense are often suggested to help explain aggressive behavior in dogs, especially aggression directed against humans. This is a subject of considerable complexity and controversy that has been discussed at some length in Volume 2 (see *Dominance and Social Harmony* in Chapter 7). Of course, competition between humans and dogs occurs, occasionally escalating into overt aggression, but the causes of aggression are not limited to dominance-related ones (see *Antipredatory Strategy and Autoprotection versus Dominance* in Chapter 8). The relationship between humans and dogs is unique and of a different order than the relationship between dogs. Just as humans view and treat dogs differently than they treat other humans, dogs appear to have evolved specialized behaviors facilitating enhanced affiliative partnerships with human companions, often appearing to prefer contact with humans over dogs (see (see *Supernormal Attachment Hypothesis* in Volume 2, Chapter 4). Dogs have been lifted out of nature and placed into the human family by a transformative process of artificial selection, socialization, and training. Over the course of the dog's domestication, powerful evolutionary influences appear to have mutually altered both human and canine behavior and our propensity for close affiliation with each other. As dogs and humans engaged in convergent hunting activities aimed at exploiting similar food resources, their ability to cooperate and communicate with each other probably underwent significant change. In addition to evolutionary convergence, humans and dogs may have been brought into closer affinity as the result of coevolutionary pressures selecting for social propensities and roles that enhanced their cooperation and biological fitness. Coevolution presupposes the existence of reciprocal selection pressures such that the evolution of one species is partially dependent on the evolution of another species. The close historical interaction between dogs and people seems to fulfill this requirement. Cooperative hunting and many other uses made of dogs may have exerted pronounced coevolutionary pressures gradually making dogs more like humans and humans more like dogs (Schleidt, 1999; Taçon and Pardoe, 2002). Schleidt (1998) has argued that the wolf's highly developed packing behavior, involving cooperation, risk sharing among pack members, pair bonding, and affiliative partnerships among like-gendered individuals, enabled wolves to move to the top of the food chain. By adopting wolflike social habits, Schleidt argues, early humans may have obtained a variety of advantages that enabled them to diversify survival strategies, thus becoming better equipped to exploit nature and coevolving together with the dog rise to a heightened position of power and social complexity.

Play and Affiliation

Under the influence of coevolution, humans and dogs appear to have brought play to a high level of expression. The augmented ability of humans and dogs to initiate and sustain play activities appears to be an essential trait mediating cooperative activity as well as enhancing our desire to stay in close proximity with each other. Perhaps, in the absence of the rigors and travail attendant to surviving under natural conditions, play takes on an ascendant trajectory relative to other more serious activities aimed at self-preservation. The home provides a high degree of safety and security and is highly conducive to play. Play is the living meaning and essence of the human-dog relationship; without play, there is nothing much of value left over to maintain a connected, harmonious, and friendly relationship. Play is forgiving and mediates affectionate tolerance by various means. Play contextualizes actions and exchanges in a way that *in-earnest* implications are overshadowed by an *in-fun* interpretation and abiding trust that all is just play and not what it might otherwise denote under more serious circumstances. Playful contextualization helps smooth over our mutual failings to communicate unambiguously in the language of the

other species, thereby installing an affiliative bias of trust that competes with other possible interpretations that might lead otherwise to socially disruptive behavior, including aggression. Play allows humans and dogs to interact and enjoy each other without worrying too much about the implications of interactive vagaries or ambiguous communication. Play nurtures social trust and tolerance within the context of the home. The dog's normal environment—the home—selects for playfulness, just as humans tend to select mates based on such things as a good sense of humor.

Paedomorphosis, Dependency, and Affection

In addition to playfulness, a number of other evolutionary changes occurring over the course of the dog's domestication have combined to enhance the dog's ability to bond, cooperate, and coexist peacefully with humans. These various changes are often collected under the heading of *paedomorphosis*, an evolutionary process in which youthful morphological and behavioral characteristics are retained into adulthood (see *Paedomorphosis* in Volume 1, Chapter 1). In addition to increased playfulness and dependent behavior, behavioral thresholds controlling fear and aggression have undergone significant alteration (Gariépy et al., 2001), making close interaction and affiliative partnering between humans and dogs possible. As a result of these various biobehavioral changes, dogs have generally become more tame and docile, submissive, and dependent on humans, making dogs more adaptable and responsive to human behavioral control efforts. Dogs appear to crave human contact and attention, exhibiting a comparable response to petting and praise as they do to the presentation of food as a reward for cooperative behavior (Fonberg et al., 1981). Tactile gratification and willing submission to human authority are highly prepared propensities in the vast majority of dogs. Dogs appear to be equipped with specialized adaptations that enable them to cope effectively with social stressors. Many dogs are so docile and compliant that they will endure intense physical pain and threatening restraint without resorting to aggression, and those that do attack often do so in an inhibited sort of way. In general, dogs appear to be biologically prepared to exhibit dependent, cooperative, and submissive behavior and inhibit disruptive competition and aggression toward humans. Perhaps, most significantly, with respect to the dog's tolerance for aversive stimulation and readiness to submit, is an innate and socially actualized propensity to recognize humans as a source of safety and comfort.

Enhanced Communication Abilities

In addition to docility, dependency, and playfulness, dogs are highly responsive to human communication—a propensity that enables them to form close cooperative bonds and work under the direction of people in a wide variety of occupations. Most dogs appear to assign meaning to human actions; that is, they view much of what we do in relation to them as having significance and value as information (Soproni et al., 2001). Dogs have been shown to exhibit a pronounced ability to follow directional cues provided by gaze, pointing, and attend to extremely subtle movements (see *Nora, Roger, and Fellow: Extraordinary Dogs* in Volume 1, Chapter 4) (Candland, 1993). Further, although dogs possessing a propensity for playful environmental exploration are capable of independent problem solving of a high order (Sarris, 1938–1939), they are apt to defer to human guidance rather than rely on their own initiative to solve problems when a human is present (Topál et al., 1997). As a result of their enhanced dependency and reliance on human guidance, dogs appear to have acquired a highly sensitive faculty for responding to and giving directional cues. Dogs use a variety of human signals (e.g., pointing, bowing, head nodding, head turning, and gaze) to locate hidden food (Miklósi et al., 1998; Hare and Tomasello, 1999). Well-socialized dogs are also capable of getting us to help them solve problems by employing various *showing* strategies, whereby they simultaneously attract our attention and direct it to some object or place of interest (Miklósi et al., 2000). Showing is accomplished by bodily orientation and gaze alternation in which

dogs look back and forth between the owner and the place or object of interest. Dogs often combine gaze alternation with vocalization, apparently in an effort to capture and direct the owner's attention to the object or activity of interest. For example, dogs commonly engage in showing behavior, when they want to go outside to play or relieve themselves, by barking or alternately looking at the owner and glancing toward the door or leash hanging on a hook.

A dog's ability to exploit human attention as something to use to achieve private ends, together with its ability to follow human directional cues accurately, suggest the existence of a high degree of social attunement and appreciation of humans as a source of information and environmental control. Dogs appear to be cognizant of the functional significance of attention as a means to enhance their control over the environment, perhaps reflecting an underlying evolutionary change associated with domestication, whereby assessment of information (attention) and intelligent hesitation (impulse control) are brought to the forefront, while spontaneous instinctive action, depending on the activation of innate releasing mechanisms, is pushed into the background. By becoming reliant on attention and impulse control, dogs are exposed to a double-edged sword offering great potential for benefit or harm (see *Locus of Neurotogenesis* in Volume 1, Chapter 9). Behavior regulated by attention and impulse control may be highly adaptable and effective in environments that are relatively predictable and controllable; however, if the environment is deranged, then dogs risk experiencing high levels of anxiety and frustration, potentially leading to increased irritability, intolerance, emotional and behavioral reactivity, and disorganization.

Emotional Command Systems and Drive Theory

Panksepp (1982 and 1998) has described four major emotional command systems mediating behavior: seeking, fear, panic, and rage (Figure 6.2). These various emotional command systems share modulatory interconnections that interact to mediate adaptive behavior. Emotional balance and organized activity are achieved by the complementary excitatory and inhibitory influences produced by these various systems working together in relative harmony. For example, the seeking system is influenced by positive incentives and appetitive behavior, activities that becomes less active as the result of satiation (feedback) or as the result of inhibitory influences produced by other emotional systems. Activation of the fear and rage system exerts a strong inhibitory effect on the seeking system; for example, fearful or enraged dogs typically refuse food. Also, fearful dogs are less likely to explore the environment for reward, but may become highly vigilant for signals of punishment. Under the influence of conflict-related stress, the seeking-rage axis may become progressively disorganized [unstable extravert (choleric or c type)] and susceptible to frustration-related compulsions (e.g., tail chasing) and aggression problems. On the other hand, the stressful activation of the fear-panic axis [unstable introvert (melancholic or m type)] may result in increased phobic reactivity, separation distress, and anxiety-related compulsions (e.g., excessive licking) (see *Inclusion Criteria* in Chapter 5).

Drive as a Higher-order Class of Behavior

Panksepp's emotional command systems closely correspond to the basic components of drive theory. According to drive theory, dog behavior can be divided into four interconnected primary drives: prey drive (social bonding/seeking system), social drive (panic system), defense drive (fear system), and fight drive (rage system). Drive pertains to a higher-order class of behavior containing a set of sequences or routines sharing a common motivational substrate and function (see *Higher-order Classes of Behavior* in Volume 1, Chapter 7). The nature of drive as a higher-order class of behavior denotes broad scope and biogenetic significance. In contrast to simple reflexive behaviors that are elicited by conditioned and unconditioned stimuli, drive-related behavior consists of complex species-typical sequences and routines that are educed (from Middle English *educen*, to direct the flow of; also, Latin *educere*, to lead)

and guided into expressions and form. Behaviors belonging to the same class are normally educed by a common set of learned or innate triggers subserving the drive function. For example, behaviors belonging to the higher-order class subsumed under the prey drive share with one another (among other things) the motivation to chase and grab moving things. The performance of drive-related behavior is frequently intrinsically reinforcing for dogs; for example, finding and taking food or detecting and escaping/avoiding a threat are strong sources of reward. Drive activities possessing less tangible sources of gratification are also often highly reinforcing for dogs to perform (e.g., chasing a ball or playing tug games).

Social play is a special modal activity wherein integrative projects are rapidly exchanged between play partners to produce

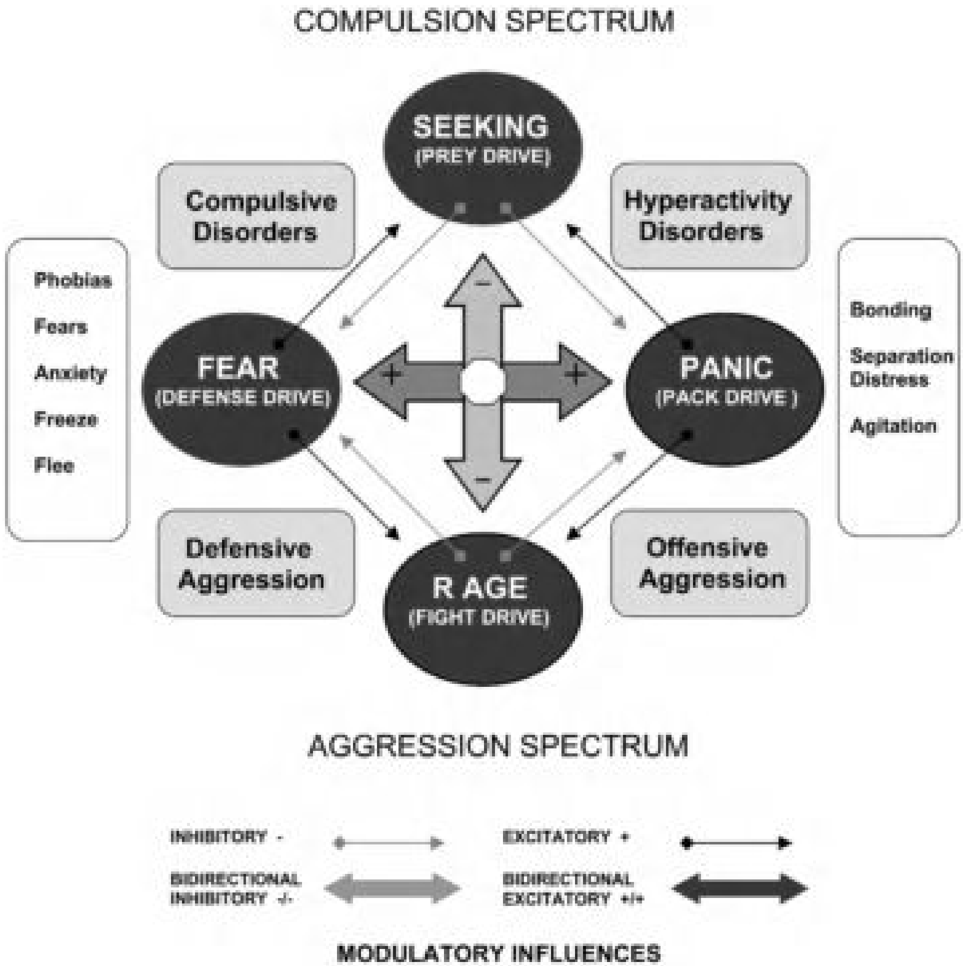

FIG. 6.2. Drive and emotional command system. According to Panksepp, behavior is under the influence of four interactive emotional command systems involving fear, seeking, panic, and rage. Panksepp's emotional command systems closely correspond to the traditional drive or instinct systems ascribed to dog behavior by trainers (see Most, 1910/1955). The activation of these various systems exerts an excitatory or inhibitory effect on other systems. The seeking and rage systems exert a reciprocal inhibitory effect, whereas fear and panic produce a reciprocal excitatory effect. Panksepp's system provides a framework of scientifically validated neurobiological influences for understanding the dynamic interrelations between emotional systems and the expression of adaptive and aberrant behavior.

mutual surprise and excitement conducive to elation and joy. Play-guided training exerts pronounced influences on the expression and form of drive-related behavior. Under the influence of ludic-establishing operations (see *Establishing Operations* in Chapter 1), sequences of behavior belonging to one drive class can be linked with behavior belonging to other drive systems, resulting in unique combinations and forms. Through the agency of play and conditioning, predatory sequences may be educed in combination with a variety of other behaviors belonging to other drive systems (e.g., social, defense, and fight). This process is most plainly apparent in the training of working dogs, whereby innate drive systems and behaviors from diverse origins are combined and harmonized into functionally useful routines via the combined influences of play, drive eduction, and conditioning. *Drive conditioning* refers to a process whereby drive-related activities are progressively focused, refined, redirected, or suppressed via the educement of other drives. The training process serves to shape and playfully entrain drive-related behaviors under the influence of ludic-establishing operations, giving their performance a high degree of intrinsic reward value for dogs. Behavioral thresholds controlling the eduction of drive-related behaviors are affected by both biogenetic and ontogenetic influences. As a whole, an individual dog's propensity to behave in drive and the behavioral thresholds controlling the eduction of drive activity are the elemental dimensions of a dog's temperament. In addition, a dog's trainability is determined by its capacity for playful drive eduction and the entrainment of the drive-related behavior needed to serve the training objective. From the cynopraxic point of view, training incorporates play and drive eduction as a source of intrinsic motivation with the purpose of actualizing a dog's potential and enhancing the human-dog relationship. Play is the substance and means to attain cynopraxic joy.

Drive Systems, Aggression, and Behavior Problems

The seeking system or prey drive consists of appetitive activities involved in searching for food (hunting and tracking), capturing and killing prey, and feeding. The searching system is also involved in the mediation of various grooming (self-stimulatory) activities (e.g., licking, scratching, and biting). The seeking system recruits various forms of locomotor activities (walking, running, stalking chasing, pouncing, and shaking) and sensory modalities (visual, olfactory, and auditory). Seeking behavior is controlled by a variety of reflexive and positive incentive systems influencing environmental exploration, excitement, and learning. When the seeking system is suppressed, its ability to restrain fear, panic, and rage may be impeded. Bilateral ablation of the olfactory bulbs results in increased emotional reactivity and aggressive behavior, suggesting that olfactory tracts projecting to the amygdala and hypothalamus may perform an inhibitory function over excessive emotional and aggressive arousal (Cheal and Sprott, 1971). This finding is consistent with the general inhibitory effect that the seeking system is believed to exert over the rage system.

Preparatory behaviors (e.g., sniffing, scanning, searching, and stalking) belonging to the prey drive system are under the influence of a positive feedback mechanism that makes their performance intrinsically reinforcing for dogs. Working dogs that track persons or search for hidden substances may be motivated to continue despite adverse reinforcement conditions because the olfactory incentive system keeps them going in the absence of immediate extrinsic rewards (see *Autonomic Arousal, Drive, and Action Modes* in Chapter 10). Under the influence of stress associated with excessive conflict or frustration, the seeking system may become pathologically overactive, leading to various disorders associated with behavioral excess and impulsivity (e.g., hyperactivity and compulsions). The seeking system is under the opposing or inhibitory influence of the rage system or fight drive. The axis between seeking and rage normally mediates reciprocal inhibition, keeping both systems in relative balance and stability. Under adverse conditions, the seeking-rage system may become unstable and disordered, perhaps by forming disruptive excitatory interconnections with fear and panic systems.

The fear system (defense drive) mediates escape/avoidance behavior (freezing and fleeing). The panic system (social drive) is activated by loss of social contact (separation distress) and is associated with agitation and intense care- and proximity-seeking behavior.

In addition to mediating reactive separation distress following the loss of social contact, the panic system is activated by the loss of social safety and trust. The axis between the panic and rage systems appears to mediate offensive aggression via the evocation of anger (see *Loss of Safety, Depression, Panic, and Aggression* in Chapter 7). Frustration and irritation preferentially arouse the rage system, triggering affective attack, biting, and fighting. A prominent factor associated with owner-directed aggression appears to be conflict associated with the loss of safety. Owners, as both attachment figures and disciplinarians, are prone to represent some degree of conflict to dogs. Normally, dogs are reared with a significant amount of training and exposure to varying degrees of aversive handling and stimulation that prepares them to cope with adversity at the hands of owners without losing their trust or sense of safety. However, in some cases, involving a history of aversive stimulation resulting in the evocation of significant physical discomfort (irritability) or repeated resource loss (frustration), heightened levels of conflict and loss of social safety and trust may ensue. Alternatively, and perhaps more frequently, dogs that have been raised permissively and indulgently, having not been properly socialized and habituated to the adversities and vicissitudes of social life, may overreact to minor intrusions, as if their social safety and trust toward the owner had been violated. And, of course, it has been violated, at least with respect to the dog's expectations of safe and trusting interaction. As the result of excessive dependency, such dogs may be especially vulnerable to panic-anger conflict in response to the owner's relatively innocuous intrusions. Many of these dogs have never been physically punished in their lives. Aversive stimulation, which obviously is relative, at the hands of a familiar and affectionate attachment figure may generate significant panic-anger conflict and autonomic arousal that, in some cases, may result in panic-evoked aggression. Although familiarity and affection are natural and powerful inhibitors of aggression, insofar as they promote social safety and security (trust), they also appear to represent the necessary conditions for panic-evoked aggression. The sufficient condition for panic-evoked aggression is a violation of trust and a loss of social safety. Dominance-related aggression frequently is exhibited in ways that are consistent with a panic-evoked scenario in which the bond between the owner and the dog is threatened by a loss of safety and trust. Fear-related aggression, on the other hand, does not depend on social familiarity, but results in situations in which preferred escape or avoidance actions are blocked or unavailable. If successful, fear-related aggression may become a preferred means to control similar threats in the future. Approach-avoidance conflict associated with strangers and territorial transitions is prone to evoke defensive aggression (e.g., bark threats, lunging, and snapping).

In combination, these various emotional command systems and the neural circuits supporting their activity have evolved under environmental and social pressures held relatively constant over the course of the dog's phylogenetic history. Appropriate species-typical behavior patterns (instinctive activities) are intimately related to these emotional systems and their activation. The natural triggers activating command or drive systems are strongly influenced by genetically encoded thresholds and self-regulating feedback mechanisms. In addition to activation resulting from unconditioned stimulation, emotional command systems may be brought under the selective control of novel triggers or conditioned stimuli as the result of classical conditioning. Although behavioral thresholds are strongly influenced by biogenetic factors, the excitatory and inhibitory thresholds controlling drive-related behavior are variable and responsive to modification and modulation through learning. Hunger, pain, thermal extremes, fatigue, and other sources of biological need produce significant modulatory influences over emotional drive systems. Chronic and acute stress can exert a particularly pervasive effect on the conditioned and unconditioned excitation or inhibition of emotional command systems.

Under the influence of acute and chronic emotional stress, the various thresholds controlling the seeking, panic, rage, and fear command systems may undergo significant change, making behavior dependent on those systems more unstable and disorganized. Stress, however, also exerts highly beneficial and adaptive effects on behavioral thresholds and learning. Upon recognizing that a disjunction exists between what the dog expects to occur and what occurs in fact, surprise or startle is evoked, enhancing its attention to the event and increasing its readiness for behavioral change. Surprise and startle mediate significant modulatory influences over trigger thresholds controlling emotional activity. In the case of surprise, fear and rage thresholds may be significantly elevated, whereas seeking thresholds may be lowered and activated in order to exploit the unexpected resource maximally. On the other hand, startle may elevate seeking thresholds while lowering fear, panic, and rage thresholds, depending on the sort of trigger stimulus involved. Beneficial stress associated with startle may help the animal escape or avoid dangerous situations by rapidly lowering thresholds of emotional command circuits controlling species-typical defensive reactions (see *Species-specific Defensive Reactions and Avoidance Training* in Volume 1, Chapter 8). In both cases, the alteration of emotional thresholds serves to compel the animal into specific courses of action, defining in advance the sort of behaviors most likely to occur and to undergo reinforcement if they do occur (see *Antecedent Control: Establishing Operations and Discriminative Stimuli* in Volume 1, Chapter 7). However, under stressful circumstances in which the dog's normal coping efforts fail because of environmental or social constraints, emotionally reactive and unorganized behavior may emerge.

Cognition and Emotional Command Systems

Emotional command systems are modulated by cortical control systems that process experience and prepare dogs to act in ways consistent with past experience on ongoing events. Under optimal conditions, prediction-control expectancies are formed that promote adaptive behavior, but, under the influence of disorderly environments, faulty expectancies and dysfunctional behavior may develop. Particularly malignant influences may originate in traumatic events or result from habitual exposure to social and environmental events that lack adequate predictability (resulting in anxiety) or controllability (resulting in frustration). A lack of predictability over significant appetitive and aversive events may disrupt emotional activity associated with the fear-panic axis, possibly contributing to the development of phobias, compulsive disorders, and separation problems. On the other hand, a routine lack of controllability over significant events may adversely affect activities mediated by emotional circuits associated with the seeking-rage axis, perhaps playing a role in the etiology of various forms of affective aggression and behavioral excesses. When behavioral events are relatively predictable and controllable, emotional command systems function optimally to promote adaptive behavior and a better state of being. However, when behavioral events occur independently of a dog's ability to predict or control them, then various pervasive cognitive and behavioral perturbations may follow (see *Learned Helplessness* in Volume 1, Chapter 9). Another source of disturbance is the conflict resulting from the simultaneous activation of incompatible emotional command systems by the same stimulus—a common occurrence in the case of severe and unpredictable punishment, whereby the owner becomes an object of both affection and fear. Lastly, early socialization and habituation efforts may exert profound and lasting influences on the activity of emotional command systems. Whether such ontogenetic influences result in the development of abnormal coping behavior appears to depend on biogenetic influences (e.g., temperament traits) affecting the way the dog processes and responds to environmental adversity. Many dogs are exposed to suboptimal and stressful environments, but only some of them ultimately develop behavior problems. Furthermore, some dogs may exhibit severe problems in the absence of a known history of significant stress and may continue to do so despite improved social interaction and environmen-

tal enhancements, underscoring the important role played by heredity in the etiology of certain behavior problems.

Modulatory and Unifying Effects of Play

The activation of care (contact comfort and affection) circuits and play drive (joy system) produces significant modulatory effects on primitive emotional command systems. Tactile stimulation has been shown to restrain aversive arousal associated with stressful situations (see *Effects of Touch* in Volume 1, Chapter 4). Contact comfort associated with touch exerts an inhibitory influence over both fear and panic (separation distress), apparently by mobilizing a potent oxytocin-mediated antistress response (Uvnäs-Moberg, 1998a; Holst et al., 2002; Lund et al., 2002). In addition, somatosensory stimulation may enhance social familiarity and exert a significant inhibitory effect over aggression (Panksepp, 1998). The usefulness of petting and affectionate praise has been well established in dog training. Play offers many therapeutic benefits for the management of arousal and behavioral output deficiencies and excesses associated with emotional command systems. The eduction of modal play enables trainers to access species-typical motor subroutines that are normally under the exclusive control of specific emotional command systems. Playing fetch appears to access behavior associated with the seeking system (prey drive), whereas tug and roughhousing games may access behaviors associated with the rage system (fight drive) while remaining in the play mode. Under the influence of play, virtually the entire repertoire of motor and expressive actions associated with threat (snarling, growling, and barking) and attack (lunging, biting, and shaking) can be evoked in many well-trained dogs with little risk of a scratch to bare skin. The activation of modal play can help a dog overcome a variety of the fears associated with new places and things, whereas activation of social modal activities (care seeking, following, and begging) can be used to reduce social inhibitions, aversions, and aggression. Play therapy specifically aims to access these various behavioral and emotional systems in order to modify activity associated with them. Combining play therapy and training provides an extremely powerful means for modifying dog behavior and enhancing social trust. Virtually all training and behavior-modification efforts take place with the dog *in drive*, that is, in a phylogenetic mode of activity, whether it be food reward (seeking system), escape/avoidance (fear system), praise and petting (social bonding/panic system), or aggressive play (rage system). Modal play is unique in that it is able to recruit activity from a variety of emotional systems and produce unique variations and modifications through learning (i.e., projects), helping to bring these diverse elements and novel connections into harmony. In doing so, play appears to liberate species-typical behavior patterns from primitive emotional systems, allowing dogs to safely practice skills and engage in novel projects that might not otherwise occur. Play promotes the activation of affects associated with enhanced harmony, balance, and joy (see *Fair Play and the Golden Rule* in Chapter 10).

Play appears to be inhibited by increasing levels of aggression or heightened exploratory or seeking activity, as well as fear and social loss. As play approaches the extremes of evoking actual aggression, fear, or separation distress, it is rapidly inhibited:

> Play may help animals project their behavioral potentials joyously to the very perimeter of their knowledge and social realities, to a point where true emotional states begin to intervene. Thus, in the midst of play, an animal may gradually reach a point where true anger, fear, separation distress, or sexuality is aroused. When the animal encounters one of these emotional states, the playful mood may subside, as the organism begins to process its predicaments and oppositions in more realistic and unidimensional emotional terms. (Panksepp, 1998:283)

Play is most likely to occur in familiar places and between familiar persons and dogs (Mitchell and Thompson, 1990). The balancing effects of play make it useful in the treatment of a variety of behavior disturbances. Play therapy is particularly useful in the management and treatment of behavior problems involving social stress and impulsive behavior. Like play, behaviors associated with drive

appear to be maintained by motivational states immediately produced by behaving in drive. The mere opportunity and *choice* to behave in drive appears sufficient to support the future occurrence of the behavior, and, consequently, drive-related behavior does not depend on reinforcement derived from other activities (e.g., obtaining food or affection), that is, extrinsic or adventitious sources of drive gratification. Behaving in drive is intrinsically reinforcing and self-perpetuating.

Adaptive Coping Styles: Play, Flirt, Forbear, and Nip

During the process of domestication, selection pressures appear to have favored a genotype expressing a configuration of neuropeptides, neurotransmitter, and receptors conducive to a highly adaptable and sociable canine phenotype. These evolutionary changes at the neurobiological level are assumed to exert a profound organizing effect at the social level, shifting behavioral thresholds toward increased tolerance (e.g., elevating fight and flight thresholds) and affiliation (e.g., lowering care-seeking and care-giving thresholds), altering the dog's responsiveness to social signals, perhaps making the human a supernormal stimulus for bonding and forming friendly relations (see *Supernormal Attachment Hypothesis* in Volume 2, Chapter 4). This general hypothesis is supported by neurobiological and behavioral changes exhibited by silver foxes selected for tameness (see *The Silver Fox: A Possible Model of Domestication* in Volume 1, Chapter 1). Tame foxes express a significantly altered hypothalamic-pituitary-adrenal (HPA) system, exhibiting reduced reactivity to social stressors; they also show evidence of increased serotoninergic and catecholaminergic activity conducive to enhanced impulse control and a reduction of defensive behavior.

Under natural circumstances, animals expressing elevated fear and aggression thresholds would be at considerable risk and disadvantage with respect to mobilizing defensive measures against threats; under the protective influence of domesticity, however, such a pattern of reduced fear and aggressive reactivity would be an advantage to a dog, whereas an opposite pattern of heightened flight-fight system (FFS) activity would be highly problematic and incompatible with domestic relations and activities. In response to the unique social stressors experienced by dogs living in close association with people, dogs appear to have evolved novel adaptations enabling them to live in harmony with human companions. The dog's capacity to form social bonds with humans is of such magnitude that it overshadows social attraction toward other dogs, even its mother (see *Maternal Separation and Stress* in Chapter 4). Under contemporary circumstances, this ancient adaptation is a mixed blessing for the average dog left alone all day. Such dogs are at a risk of developing insecure or excessively strong and exclusive social attachments, making them vulnerable to suffer distress at separation. During the dog's early domestication, staying close to its keepers would have been a source of security, with the human keeper taking on the role of benefactor and protector (tend-and-befriend adaptions), allowing human and dog to form close bonds, and allowing the protodog to progressively shed its FFS reactivity and evolve flirt-play and forbear-nip adaptive strategies. In an important sense, when a dog is left alone, it loses its guardian shield of protection and security.

Phylogenesis, Polymorphism, and Coping Styles

Dogs appear to have evolved two relatively independent but overlapping and complementary defensive systems and styles for coping with disappointing, threatening, stressful, or aversive social situations. These hypothetical systems are present in varying degrees in all dogs, depending on heredity and activating experience. The adaptive coping styles (flirt-play and forbear-nip) are largely composed of the self-preservative and self-protective strategies of the young, reflecting a paedomorphic social adaptation. When presented with a threatening social situation, such dogs tend to exhibit an admixture of two general patterns: (1) stable introversion, a variety of attention-seeking, care-seeking, and submissive behaviors (not necessarily authentic), a genuine appetite for and enjoyment of close social

contact and interaction, and a passive "grin and bear it" strategy to aversive stimulation or escape when pushed too far; or (2) stable extraversion, showing a genuine love of rough-and-tumble play and object play, a variety of playful escape and evade tactics, and a "bite the bullet" strategy to aversive stimulation or inhibited nip when pushed too far. The vast majority of dogs appear to combine these various adaptive strategies in varying proportions to form adaptive coping styles with which to manage stressful interaction with human companions. For the sake of simplicity, the term *flirt-and-forbear* system is used to designate this antistress, antifear, and antiaggression system of domestic adaptations.

In addition to fostering a heightened capacity for social affiliation, cooperation, and play, novel physiological mechanisms have evolved to support the flirt-and-forbear and tend-and-befriend styles of human-canine adaptive coping and bonding. Although the exact neurobiological substrates integrating these adaptive coping styles are not known, phylogenetic changes to the oxytocin-opioidergic system, the serotonergic stress-management system, and the dopaminergic reward system appear to be likely focal points of coevolutionary change. In any case, biobehavioral changes conducive to enhanced playfulness, social reward, social cognition, and emotional adjustment appear to have taken place in a process of phylogenetic enculturation, to borrow and extend Hare's term (Hare et al., 2002), whereby humans and dogs have mutually accommodated the other via a unique coevolutionary process (see *Coevolution, Play, Communication, and Aggression*). Over the course of 135,000 years of coevolution (Vilà et al., 1997), humans and dogs appear to have exerted a profound social and emotional transformation upon one another, mutually evolving changes conducive to close affiliation. Many of these changes appear to have taken place in the direction of social, cognitive, and behavioral neoteny; that is, humans and dogs have coevolved in a way that has caused each species to retain more juvenile characteristics into adulthood (see *Paedomorphosis* in Volume 1, Chapter 1), giving rise to our mutual appreciation and capacity for affection and our love of play, among other things. As incredible as the notion may seem, the human-dog capacity for affiliative bonding and play appears to be organized and integrated at the level of mutual modifications of the human and canine genome, a phylogenetic testament to an ancient and perennial bond etched forever into our respective genotypes, as friends might scrawl their initials side by side on an old tree.

Accordingly, humans and dogs appear to have evolved complex and genetically polymorphic adaptations as the result of this evolutionary convergence and phylogenetic enculturation process—changes that should be evident in the matrix of physiological and neurobiological processes from which social cognition, emotion, and adaptive coping styles emerge. This general theory suggests that among dogs there is not a single species-typical nature, but rather an assortment of multiple canine natures that emerge under the influence of polymorphic variations, ontogenetic stressors, and epigenetic organizing influences (see Bittner and Friedman, 2000). Biological adaptations conducive to harmonious human-dog interaction are expressed at the level of an infinitely complex array of biogenetic and neurobiological processes from which functional and structural systems of biobehavioral organization gradually emerge, giving rise to the capacity for cognition, emotional, and the capacity to adapt by means of learning and goal-oriented initiative. Of particular interest from the practical vantage of cynopraxic training and therapy are the neurobiological changes that resulted in the development of the previously discussed canine adaptive coping styles.

Oxytocin-opioidergic Hypothesis

Brown and colleagues (2001) may have discovered a potentially significant link pertaining to the dog's adaptive abilities and capacities for social attachment and bonding in a unique modification of the canine oxytocin-opioidergic system. As discussed in Chapter 4 (under *Maternal Separation and Stress*), oxytocin and endogenous opioids appear to interact in the process of forming social attachments. Opioids also play a major role in

modulating distress and pain. In adult animals, opioids appear to exert an inhibitory effect on central and peripheral oxytocin release. In dogs, however, opioids appear to inhibit central oxytocin release while at the same time stimulating peripheral release—a phenomenon that appears to be unique to dogs. The physiological implications of this finding are not clear, but given the strong correlation between increased peripheral oxytocin activity and social approach, attachment, and antistress effects, this apparently novel adaptation may contribute to the dog's ability to cope physiologically with social stressors unique to living in close association with humans. Oxytocin appears to exert an agonist effect on endogenous opioid activity (Lund et al., 2002), and facilitates exogenous opiate activity by reducing tolerance effects and by attenuating withdrawal symptoms (Sarnyai and Kovacs, 1994). Oxytocin has also been shown to enhance active avoidance learning, perhaps by reducing emotional arousal (Uvnäs-Moberg et al., 2000). Together with arginine vasopressin (AVP) and corticotropin-releasing factor (CRF), oxytocin appears to play a role in the acute integration the stress response, but after repeated release of oxytocin, perhaps in association with endogenous opioids, mediates an antistress and calming effect (e.g., reduces anxiety, decreases blood pressure, and decreases glucocorticoid release) (Uvnäs-Moberg, 1997), whereas AVP and CRF continue to mobilize stress-related physiological changes conducive to increased anxiety, glucocorticoid release, and blood pressure.

Uvnäs-Moberg and colleagues (1997 and 1998a and b) at the Karolinska Institute, Stockholm, have intensively investigated the antistress effects of oxytocin, reporting several lines of compelling evidence in support of the antistress hypothesis. Peripheral oxytocin promotes parasympathetic normalization via enhanced vagus-nerve tone, modulates irritability, decreases sympathetico-adrenal tone, promotes anabolic metabolism, and exerts a calming effect and a host of other effects consistent with an antistress function. For example, oxytocin plays a central role in the regulation of heart rate and coronary flow, cardiovascular effects that are mediated by oxytocin terminals acting on the vagus nerve at the level of nucleus of the solitary tract (Higa et al., 2002) and by means of a direct bradycardial action on the heart itself, among other routes (Petersson, 2002). The central and peripheral effects of oxytocin on canine blood pressure and heart rate are complicated, with oxytocin and AVP appearing to have complementary roles in the regulation of cardiovascular activity (Montastruc et al., 1985). Although the blood-brain barrier shows a low permeability to oxytocin, some passive transport may occur in the case of high peripheral concentrations in association with injections (Ermisch et al., 1985; Uvnäs-Moberg et al., 2000).

Together with cardiovascular benefits, peripheral oxytocin appears to enter the brain to exert a negative-feedback effect on FFS arousal, thereby mediating a calming influence and elevating thresholds associated with irritability and pain (Lund et al., 2002). In addition to antinociceptive effects occurring at the level of the periaqueductal gray, systemic administration of oxytocin has been shown to increase central α_2-adrenoceptor responsiveness at the level of the locus coeruleus (Petersson et al., 1998), the amygdala, and the hypothalamus (Diaz-Cabiale et al., 2000). Although generally excitatory, norepinephrine (NE) acting at α_2-adrenoceptor sites produces a potent inhibitory effect, appearing to play a crucial role in helping dogs to cope adaptively to social stressors by preventing or ameliorating stress-related dysregulation at the level of the prefrontal cortex (Birnbaum et al., 2000).

Oxytocin is hypothesized to play a major role in the expression of somatic feelings of enhanced comfort and safety (well-being) resulting from the occurrence of conditioned and unconditioned rewards (e.g., vocal encouragement, petting, and food) obtained in the process of adaptive control efforts (see *Origin of Reactive versus Adaptive Coping Styles* in Chapter 4). The social benefits of oxytocin appear to be cumulative, developing as the result of repetitive stimulation of oxytocin release. The oxytocinergic benefits of petting and food rewards appear to exert a potent therapeutic effect over stress, fear, and aggression. On the other hand, complementary dopamine reward circuits appear to encode

cerebral teaching signals that optimize adaptive control efforts by means of detecting and coding positive prediction discrepancies (Schultz, 1998), thereby mediating surprise and cortical reward, play, active modal strategies (e.g., exploring, experimenting, and discovering), and feelings of joy and freedom.

Not all dogs respond to petting with a decreased heart rate, but those that do are also responsive to petting as a reward (Fonberg, 1981). Dogs that exhibit an increased heart rate when petted are typically unresponsive to petting as a reward. Manual restraint also appears to exert a significant heart-rate deceleration effect in dogs, perhaps as the result of parasympathetic rebound effects, a cardiac effect that may be amplified by petting. In the case of nervous pointer dogs, restraint-induced deceleration is not appreciably enhanced by petting (Thomas et al., 1972). These findings suggest that petting may offer a valuable diagnostic tool for differentiating dogs exhibiting adaptive versus reactive coping styles. Dogs responding to petting with an increased heart rate may be vulnerable to stress associated with the activation of the FFS and show an increased propensity for emotional reactivity, social avoidance, and defensive behavior, traits consistent with reactive vulnerability, whereas dogs showing a reduced heart rate when petted may exhibit an antistress response consistent with an adaptive coping style, correlating with traits such as friendly approach and attachment, social dependency, playfulness, and calm. Kostarczyk (1991) found that the administration of atropine to dogs results in significant heart-rate acceleration and abolishes petting-related cardiac deceleration, with dogs becoming avoidant of petting and showing increased excitability, tenseness, and aggressiveness—results consistent with the loss of oxytocinergic regulatory influence over parasympathetic functions. Atropine is a potent oxytocin antagonist shown to block oxytocinergic-mediated bradycardia (Mukaddam-Daher et al., 2001). The reactive emotional responses exhibited by dogs medicated with atropine appear to reflect a loss of control over sympathetic arousal, at least in part due to blocking the antistress effects of oxytocin. As previously mentioned, massagelike tactile stimulation appears to mediate an antinociceptive effect via increased levels of oxytocin at the level of the periaqueductal gray (PAG) (Lund et al., 2002) (see *Neural Circuits Mediating Anger and Rage*). This finding underscores the value of posture-facilitated relaxation (PFR) training for helping to attenuate irritability and contact intolerance.

Cyonopraxis, Antistress, and a Tend-and-Befriend System

Cynopraxic training is performed with the goal of reducing interactive conflict and tension arising from antagonistic control interests. Instead of reacting in accordance with the FFS when exposed to social stressors associated with owner limit-setting actions and periodic separations, the dog learns to adjust to stressors under the calming influence of the flirt/play-forbear antistress system. Cynopraxic therapy organizes interactive transactions and emotional exchanges between the owner and the dog with the goal of bringing a flirt-and-forbear antistress system on-line. The compromise and mutual appreciation associated with cynopraxic training promote interactive harmony and friendly interaction akin to what Taylor and colleagues (2000) have referred to as *tend and befriend* adjustments; unfortunately, the authors seem to assume that such a capacity is the special providence of the female nervous system. On the contrary, the potential for adaptive organization in accordance with the tend-and-befriend system is probably the result of an asexual neural plasticity shared by both male and female humans alike, perhaps arising in the course of human-canine coevolution, giving human beings the capacity for affectionate bonding, supportive and comforting interaction, and intensified feelings of well-being as the result of bonding and sharing a home with a dog. According to this hypothesis, both humans and dogs have jointly evolved specialized antistress capacities conducive to close social interaction and affectionate bonding.

Cynopraxis is essentially an expression of the human capacity to tend (provide the dog with an improved quality of life) and befriend (establish and enhance the human-dog bond), a capacity that dogs learn to reciprocate as the result of socialization and training. The natural orientation of the

human being toward the dog is one of tending and befriending, whereas the dog has evolved a heightened capacity for dependent behavior and friendly reciprocity, operating under the influence of an antistress, antifear, and antiaggression system evolved to cope with stressful interaction and conflict associated with close association with humans, viz., a flirt/play-forbear-nip or, more simply, a *flirt-and-forbear* system. Although male dogs appear to exhibit a greater propensity (as a group) for reactive adjustments in association with the activation of the FFS than do females, under the influence of play, reward-based training, and social interaction conducive to the activation of the flirt-forbear system (e.g., human tending and befriending), both male and female dogs show an extraordinary capacity for adaptive coping and adjustment, allowing the natural canine aptitude for reciprocating human tending and befriending behavior to emerge in the form of interactive harmony, mutual appreciation, and a loving and trusting bond.

Olfaction and Emotional Arousal

Olfaction appears to play a major role in the process of emotional learning and memory. The importance of olfactory learning on emotional behavior is suggested by neuroanatomic evidence showing that olfactory projections reach the amygdala more directly than do other sensory inputs. In addition, olfactory stimuli appear to form rapid and lasting conditioned associations with both attractive and aversive emotional states—associative learning that is mediated from an early age by the amygdala (Sullivan and Wilson, 1993). Oddly, though, neonatal rats exposed to odor-shock conditioning prior to postnatal day 10 show a paradoxical approach response toward the odor instead of avoiding it as one might expect. After day 10, rat pups learn to avoid the odor as the result of aversive conditioning, provided that they had not received prior odor-shock conditioning. Most interestingly, however, if the infant rats have been previously exposed to odor-shock conditioning, they continue to show an approach response toward it, even though they are now neurologically able to learn an avoidance response. Paradoxical conditioning resulting in persistent approach behavior toward a conditioned aversive stimulus may help to facilitate infant bonding and attachment under adverse or socially abusive conditions (Sullivan et al., 2000). These findings may help to explain the tendency of dogs to respond to aversive stimulation by emitting avoidance/escape responses and then engaging in attention-seeking and comfort-seeking behavior toward the person delivering the stimulation (Fisher, 1955) (see *Early Trauma and the Development of Behavior Problems* in Volume 2, Chapter 4). The search for safety in human contact and comfort giving appears to be a significant aspect of the bonding and socialization process.

Recalling that oxytocin exerts an antinociceptive effect (see *Oxytocin-opioidergic Hypothesis*), Ågren (1997) found that rats injected with the peptide appeared to secondarily influence the pain thresholds of untreated cagemates. Further study of the phenomena, revealed that when the untreated cagements were rendered anosmic they no longer showed the change in pain sensitivity, suggesting that olfaction may mediate the effect. This finding offers an interesting olfactory hypothesis to test with respect to the increased playfulness exhibited by puppies at weeks 5 and 7 toward female handlers (Scott, 1992a). Finally, olfactory cues might also play a role in the evident gender bias shown by dogs toward human males and females, with dogs seeming to be more friendly (Lore and Eisenberg, 1986) and less defensive and aggressive toward females than males (Wells and Hepper, 1999). These findings may also have practical value, indicating the possibility that an oxytocin-related substance with antistress properties might be secreted on the skin (sebaceous) or in the sweat of animals treated with oxytocin. Conceivably such material, if it exists, could be isolated, concentrated, and tested for antistress effects. Finally, it is interesting to speculate that some potential benefit may be derived from repeated exposure to an aerosol oxytocin mist, perhaps periodically delivered by a spray dispenser controlled by a timer and attached to a crate or kennel to assist dogs

under stress at home or while under hospitalization.

Olfaction, Fear, and Anger

Many dog owners and trainers have reported anecdotally that dogs appear to smell fear, perhaps helping to explain why some dogs react aggressively toward the diffident approach of nervous people (Sommerville and Broom, 1998). A fearful person would undoubtedly present a significantly different scent picture than a relaxed person. The belief that dogs can discriminate emotional states as the result of scent messages emanating from the pores and breath of humans has not been tested; however, it is highly likely that dogs can detect odors associated with highly emotional and stressful states. Detecting odors associated with human anger and fear would be highly advantageous to dogs. The scent aura at times of intense anger or frustration would likely produce a strong and lasting impression, especially if such odors were followed by severe physical punishment. Exposure to the odors associated with anger or fear may sensitize olfactory attentional processes localized in the amygdala—an area that that is strongly activated by the presentation of olfactory stimuli (Hudry et al., 2001) and prominently involved in emotional learning. Seizure-alert dogs may rely on scent-related changes occurring in advance of epileptic seizures, thereby enabling them to anticipate such activity (see *Ability to Detect and Discriminate Human Odors* in Volume 1, Chapter 4). Many dogs appear to react in a highly emotional manner to seizure activity, becoming fearful or aggressive as the result of such events (Strong and Brown, 2000). Edney (1993) found that dogs anticipating seizure activity typically exhibited signs of increased anxiety and restlessness. At such times, these dogs appeared to act strangely and were more difficult to control than usual.

Donovan (1967) has tested the hypothesis that dogs may express their anal glands in order to facilitate escape from threatening restraint. After manually expressing anal sac fluids, he presented the material to various puppies and dogs to sniff. He found that puppies showed no response to the anal fluids, whereas adult dogs "recoiled and appeared apprehensive" (1048) when presented the fluids smeared on plastic gloves:

> Dogs that previously dashed enthusiastically to the opened gate of the exercise pen, turned back as if halted by an electric shock when the gloves were held in the opened doorway. (1048)

The fact that puppies showed little reaction to the odor suggests that the fearful response might have been acquired as the result of learning. As the result of expressing anal fluids consequent to intensely threatening events, dogs may associate such odors with the fear and escape behavior that occurred at such times. When another dog, perhaps under the distress of an attack, subsequently releases the odor, it may evoke a conditioned escape response in the attacker, thereby possibly turning the attacker away and protecting the loser from injury. Similarly, the deposition of anal secretions in feces may exercise a conditioned repellent effect helping to ward off intruders. In summary, according to this hypothesis, anal fluids are not inherently repellent, but may rapidly become so as the result of aversive conditioning. The scent of anal secretions may be highly prepared for association with fear and escape behavior, making biological extracts or synthetic analogues of anal fluids potentially useful for the management of certain aggression problems (see *Threat and Appeasement Displays* in Volume 2, Chapter 8).

Chemosignals, Social Behavior, and the Modulation of Emotional Thresholds

In addition to conditioned social odors, it is reasonable to assume that various chemosignals and pheromones are exchanged between dogs to modulate emotional thresholds (motivational readiness). Social chemosignals may serve to amplify the significance of other social signals present at the time of their expression, as well as promote positive mood states conducive to friendly social interaction. These modulatory effects of olfactory signals on social behavior and mood may help to explain the significance of the canine custom of mutual anogenital presentation and exploration exhibited by most dogs during close

encounters with other dogs, especially unfamiliar ones. Chemosignals and pheromones may offer a valuable means for promoting affiliative interaction by increasing positive affect and mood while elevating aggression thresholds. Reportedly, a dominance pheromone may be contained in the cerumen of dominant dogs—a substance that appears to facilitate submission behavior in subordinates (Pageat, personal communication, 2001; Pageat, 1999). Interestingly, the steroids estratetraenol and antrostadienone have been shown to produce modulatory effects on human affect and mood consistent with a social function (Jacob and McClintock, 2000).

Olfactory Conditioning

Odors are rapidly conditioned and appear to exert pronounced effects over emotional behavior. Although experimental evidence is lacking in dogs, research with human subjects has shown that ambient odors presented during stressful or frustration-inducing experiences exert lasting effects. For example, Kirk-Smith and colleagues (1983) found that odors present while adults worked at a stressful task acquired the capacity to elicit increased anxiety when they were encountered again. Similarly, children exposed to an ambient fragrant scent while working on an insolvable maze task generating emotions of failure and frustration showed increased problem-solving deficits when exposed to the same odor while working on a solvable cognitive problem (Epple and Herz, 1999). The children exposed to the conditioned odor performed less efficiently on the problem than children exposed to another fragrant scent or no scent at all.

Olfactory conditioning for the purpose of reducing aversive emotional arousal in dogs has proven to be useful in a variety of training and behavior-therapy contexts. By pairing a dilute odor with relaxing massage and petting, or other sources of reward, relaxation, and safety, the odor stimulus gradually becomes conditioned to produce similar emotional effects independently of the unconditioned stimulus used. The close ontogenetic relationship between olfaction and tactile sensory development may prepare odors for rapid association with taction-elicited emotional states (see *Social Comfort Seeking and Distress* in Volume 2, Chapter 4). The pairing of an olfactory stimulus with taction-induced relaxation establishes a conditioned association between the odorant and relaxation so that the odor alone can either facilitate or independently evoke the relaxation response (see *Posture-facilitated Relaxation Training* in Chapter 7).

Practitioners of aromatherapy attribute special psychological and medical benefits to fragrant oils (Tisserand, 1977), but few of these claims are supported by scientific studies, especially in the case of animals (Wynn and Kirk-Smith, 1998). However, several studies in humans do indicate that aromatherapy may augment a modest and transient reduction in anxiety when combined with massage (Cooke and Ernst, 2000). Traditionally, many fragrant oils have been reputed to have relaxing and calming attributes; however, the beneficial effects of odors on mood and emotions probably depend more on conditioning than an inherent property of the scent. Some odors, though, do appear to exert benefits on mood, aversive states, and stress-related changes independently of conditioning (Shibata et al., 1990 and 1991). For example, the odor of lemon has been shown to produce an antidepressant effect in rats (Komori et al., 1995), and the odor of orange has been shown to reduce anxiety while promoting a more calm and positive mood in people receiving dental treatment (Lehrner et al., 2000). Lavender, chamomile, and vanillin have also been shown to exert central effects consistent with improved mood and anxiety reduction (see *Fear of Loud Noises and Household Sounds* in Chapter 3).

Although a particular fragrant oil may be pleasing to a human nose, it may not be equally attractive to a dog. Whatever odor is selected should not be aversive to the dog or presented at a concentration too strong for the dog's sensitive nose. The odorant should be delicate and faint to the human nose and, ideally, evoke interested sniffing by the dog. Odors that cause the dog to turn its nose away should not be used. Many dogs appear to be actively attracted to sandalwood, which

has a soft mellow quality that provides an adequate odorant for most dogs when diluted 1:30–50 in a carrier vegetable oil. Citrus odors (e.g., lemon or orange) and lavender may have some additional advantages in the treatment of separation distress, phobias, and various anxiety-related problems.

In addition to pairing an odor with taction-induced relaxation, other scents can be paired with the presentation of food rewards and other sources of attractive stimulation. A highly effective method involves putting 1 or 2 drops of a fragrant oil or extract inside a squeaker used as conditioned reinforcer. With each squeak, the odor is dispensed into the air, thus pairing the odorant stimulus with success and reward. This same odor can be presented just before feeding the dog, as well. A play odor can be developed by putting a scent on play objects or presented in advance of getting the dog's leash to go for a walk. An olfactory safety signal can be paired with the opponent relief and relaxation associated with the discontinuation of an aversive state [e.g., an odor can be delivered under the door just before concluding a time-out (TO) period]. The idea is to pair odors with activities that access specific behavioral and emotional systems having value for specific behavior-modification objectives. Conditioned olfactory relaxation, reward, and safety stimuli provide useful means to modulate emotional states associated with undesirable behavior operating under the influence of aversive arousal (e.g., frustration, fear, anger, or irritability). Finally, using scents creatively, such as training the dog to find scented play objects, provides valuable environmental enrichment and stimulation to the dog.

NEUROBIOLOGICAL REGULATION OF AGGRESSION

Stress-related Potentiation of the Flight-Fight System

Conditioned threats and stressors are processed by a complex network of reciprocal cortical and subcortical pathways, projecting to and from the amygdala, the hippocampus, the hypothalamus, the PAG, and several other areas (Panksepp, 1998). The medial prefrontal cortex appears to perform a goal-oriented appraisal function based on prediction-control expectancies and calibrated establishing operations, whereby autonomic arousal is continually matched to expected adjustment needs. In the case of aversive events, behavioral adjustments that produce better-than-expected outcomes result in de-arousal and a reduction of autonomic activation (relief and reward), whereas worse-than-expected outcomes result in increased arousal, alertness, readiness, and agitation. In the case of unpredicted or uncontrollable aversive events, subcortical pathways may rapidly mobilize neurobiological changes conducive to emergency adjustments, including the instigation of the FFS, with the release of CRF and the activation of the HPA system (see *Stress and Flight or Fight Reactions* in Chapter 4). The amygdala appears to play a central role in the orchestration of the FFS, operating in coordination with the prefrontal cortex, where executive organizing functions and activities are momentarily overshadowed by a priority to attend to immediate sensory information and to adjust rapidly to the threat. As a result, behavior output shifts from an adaptive interface, based on prediction-control expectancies and establishing operations, to a reactive interface based on species typical modal escape-attack behaviors.

Instrumental control over aversive events is reflected at the level of autonomic arousal, with blood pressure increasing in response to uncontrolled aversive events while remaining steady during signaled avoidance (Gaebelein et al., 1977). In addition, dogs that are unable to escape aversive stimulation show a significantly stronger adrenocortical stress response than dogs that are able to escape (Dess et al., 1983) or when instrumental control over an aversive event is lost (Houser and Paré, 1974) (see *Fear and Peripheral Endocrine Arousal Systems* in Chapter 3). Cook (2002) has studied the stress response of sheep when exposed to the threat of a barking dog while under an escapable condition and under a nonescapable condition. Sheep show a two-phase change in CRF concentrations in the amygdala. The first phase involves a sharp CRF spike attributed to central arousal effects, which is followed by a

slower and smaller-magnitude spike of CRF activity that closely shadows blood cortisol concentrations. Whereas the injection of a glucocorticoid antagonist just prior to stimulation had no effect on the first sharp spike of CRF, it abolished the second smaller spike, a finding that supports the hypothesis that cortisol may exert an acute activating effect on the central amygdala. The researcher found that repeated and inescapable exposure to a barking dog produced a pronounced sensitizing effect on amygdala-CRF activity when the sheep were subsequently exposed to a novel aversive event (1 second of shock).

In the case of sheep belonging to the nonescape group, a very pronounced and sustained activation of second-phase CRF activity occurred, indicating a potentiated responsiveness of the CRF neurons in the amygdala. As a result of repeated exposure to the threatening dog, the nonescape group showed signs of adapting with decreasing amounts of first-spike CRF activity, but showed a steady increase of blood cortisol levels over the course of the experiment. This evidence of habituation with regard to the first spike may indicate a modulatory prefrontal influence, whereas the increasing cortisol levels and evident sensitization of amygdala-CRF circuits may indicate a maladaptive elaboration akin to what Gannt has call schizokinesis (see *Gantt: Schizokinesis, Autokinesis, and Effect of Person* in Volume 1, Chapter 9). The sheep belonging to the escape group also showed signs of adapting in response to the acute phase of stress, and, unlike the nonescape group, the escape group showed a steady decrease of blood cortisol activity after repeated exposures to the barking dog. These findings support the hypothesis that behavioral stress associated with the loss of control over aversive events exerts a lasting potentiating effect on subsequent exposures to stressors (anticipatory anxiety), perhaps via sensitized amygdala-CRF circuits and schizokinetic elaborations. As a result, uncontrollable stressors may gradually cause dogs to become sensitized (irritable and intolerant) to aversive stimuli, perhaps causing them to respond to innocuous social threats with exaggerated emotional and reactive output that persistently mismatches executive prediction-control expectancies.

Neural Circuits Mediating Anger and Rage

The amygdala plays a prominent role in the rapid processing of ambiguous and potentially dangerous stimuli (Adolphs, 2001). Modulatory signals leaving the amygdala converge on both cortical and subcortical destinations, with amygdaloid pathways both facilitating and suppressing defensive rage behavior (Siegel et al., 1997). The pathways producing anger and rage appear to originate in the medial amygdala, whereas suppressive influences originating in the central amygdala project directly to the midbrain PAG, where inhibitory connections are formed with opioidergic receptors. The PAG mediates a variety of changes conducive to affective attack, including autonomic changes (increased respiration and heart rate), increased alertness and excitability, and facial expressions associated with threat and biting actions (Panksepp, 1998). Anger-rage pathways originating in the medial amygdala reach the medial hypothalamus via the bed nucleus of the stria terminalis (BNST). From the medial hypothalamus, the anger-rage signal is relayed to the PAG. The neuropeptide substance P appears to play a prominent role in the expression of anger and rage. Psychological stress is believed to stimulate the release of substance P in the amygdala (Kramer et al., 1998). In cats, a substance P pathway between the medial amygdala and the medial hypothalamus promotes defensive rage via interaction with excitatory glutamate neurons projecting to the PAG (Siegel et al., 1997; Gregg and Siegel, 2000)—behavior that is blocked by neurokinin 1 (NK-1) antagonists. The NK-1 receptor mediates central substance P activity and is found throughout the brain, with concentrations located within the limbic system and hypothalamus. Knockout mice lacking the NK-1 receptor show a significant reduction of territorial aggression and other measures associated with acute stress and injury (De Felipe et al., 1998). Currently, a promising orally assimilable NK-1-receptor antagonist is under development for the treatment of depression

(Kramer et al., 1998). The substance, MK-869, produces potent antidepressant effects comparable to paroxetine but with fewer side effects. Given the involvement of substance P in the mediation of aversive arousal and aggression, MK-869 may eventually prove of value in the treatment of canine aggression problems, but at the moment its clinical efficacy and safety as an antiaggression agent in dogs is unknown. Interestingly, antidepressants have been shown to downregulate the biosynthesis of substance P in rats, suggesting the possibility that the apparent beneficial effect of such medications may be due, in part, to alterations of the neurokinin system (Kramer et al., 1998).

Threatening stimuli activate the sympathetic branch of the autonomic nervous system (ANS) via various direct and indirect pathways between the amygdala, lateral hypothalamus, locus coeruleus, and sympathetic preganglionic neurons terminating in various parts of the body, with the prefrontal cortex playing a prominent modulatory role at virtually every level of central organization (see *Stress and Flight or Fight Reactions* in Chapter 4). The resulting widespread sympathetic arousal prepares the organism for emergency flight or fight action. As the result of sympathetic arousal, epinephrine (adrenaline) and NE are rapidly released into the bloodstream by the adrenal medulla (see *Hypothalamus* in Volume 1, Chapter 3). Epinephrine and NE have widespread energizing effects on the body, including pronounced effects on cardiovascular activity. Although epinephrine cannot cross the blood-brain barrier, some researchers have reported that epinephrine appears to play a significant role in the consolidation of aversive memories (see *Neural Stress Management System and Fear Learning* in Volume 1, Chapter 3). The memory-enhancing properties of epinephrine may be mediated indirectly by way of afferent vagal nerve transmissions. Le Doux (1996) has suggested that vagal afferent signals triggered by peripheral epinephrine might help to explain how epinephrine facilitates the formation of memories about aversive events. The vagus nerve at the nucleus of the solitary tract forms reciprocal connections with the hypothalamus and the locus coeruleus. The nucleus of the solitary tract performs a host of integrative functions in the process of modulating autonomic arousal via direct reflexive feedback effects on various organ systems, as well as a diffuse network of reciprocal feedback links with the lateral hypothalamus, the central amygdala, and the BNST, among other sites. The locus coeruleus is composed of NE-producing neurons that form widespread interconnections throughout the brain, including the amygdala and the hippocampus. These areas are believed to be closely involved in the consolidation of aversive memories, leading to Le Doux's hypothesis that epinephrine via vagal enervation might play a significant role in their formation. In addition to mediating the formation of aversive memories, NE has been shown to influence the expression and regulation of affective aggression (see *Monoamines and the Control of Aggression* in Volume 1, Chapter 3) (Eichelman, 1987). Defensive behavior in cats is associated with the activation of NE-producing neurons, an effect that appears to help prepare the animal to respond to threatening situations (Levine et al., 1990). Anger-induced changes in heart rate and blood pressure may activate aggression-mediating circuits (NE and otherwise) via a similar afferent vagal feedback mechanism postulated to facilitate aversive memories.

Biogenetic influences strongly affect sympathetic and parasympathetic nervous activity. These antagonistic arousing and de-arousing autonomic influences differentially affect a wide variety of behavioral thresholds, with sympathetic-dominant dogs tending to be more reactive to provocative stimulation than parasympathetic-dominant counterparts (see *Genetic Predisposition and Temperament* in Volume 1, Chapter 5). Sympathetic-dominant dogs can often be differentiated from parasympathetic-dominant ones by the degree of skeletal muscle tonus that they exhibit. The medulla mediates normal resting muscular tonus and produces tonus changes in response to sympathetic arousal. Increased muscle tonus may reflect an increased standing readiness for emergency action resulting from neurobiological predisposition and learning associated with aversive arousal (e.g., fear and anger). Dogs that exhibit the rigid muscular tonus consistent with sympathetic-dominance are often the most responsive to the muscle-

relaxing effects of PFR. Alterations in blood pressure are a sensitive indicator of autonomic tone in response to environmental and social stressors (Wilhelmj et al., 1953; Kallet et al., 1997). The expression of sympathetic and parasympathetic typologies appears to be strongly influenced by gender. Significant gender-related differences in blood pressure have been reported in dogs (N = male, 67; female, 80) and in female dogs (N = 80) (Van Liere et al., 1949), perhaps reflecting underlying gender-related autonomic differences modulating emotional responsiveness to environmental stimulation. According to the gender hypothesis, males and females may be biologically different on the level of autonomic responsiveness, with males tending toward sympathetic dominance and females being more inclined toward parasympathetic dominance. The gender hypothesis is consistent with the findings of Hart and Hart (1985), indicating that male dogs are rated to be more prone to exhibit reactive behaviors (sympathetic dominance), whereas females tend to be more affectionate and trainable (parasympathetic dominance).

Amygdala-mediated emotional interpretation of social and environmental stimulation appears to be coordinated with the impulse-control functions of the prefrontal cortex and contextualizing influences emanating from the hippocampus. Sudden change or situations requiring rapid assessment of threat may result in inappropriate aggressive responses in animals possessing a strong agonistic tone. Compromised attention resulting in startle may also precede a rapid transition from a state of vulnerability to defensive aggression. A common situation involving aggressive arousal in dogs occurs when they are disturbed while asleep or in a hypnagogic state just preceding the induction of sleep. Such dogs may misinterpret the owner's actions, and without the benefit of fully alert and functional executive attention and impulse control, they may become enraged and bite.

Autonomic Arousal, Heart Rate, and Aggression

Aggressive dogs frequently exhibit a collection of exaggerated autonomic responses to social threats, including increased behavioral excitability, panic, and fear. Canine domestic aggression (CDA) is usually expressed under the influence of significant autonomic arousal—catastrophic arousal that often appears to be out of proportion to the eliciting situation (see *Loss of Safety, Depression, Panic, and Aggression* in Chapter 7). These autonomic changes, similar to symptoms of panic, appear to take control of the dog. In significant ways, dogs that attack their owners despite the presence of strong affectionate and familiar ties resemble human perpetrators of domestic violence. In fact, panic-evoked aggression may represent a viable animal model of domestic violence. Studies investigating perpetrators of domestic violence indicate that such individuals experience intense autonomic arousal and various symptoms of panic (e.g., palpitations, fear, increased respiration, feelings of losing control, and tremors) at the time of attacks. Among dogs, enhanced control over aversive events has a potent moderating event over blood pressure, heart rate, and glucocorticoid release, whereas the loss of control exerts a pronounced disinhibitory effect on physiological markers of sympathetic autonomic arousal (Houser and Paré, 1974). Perpetrators of domestic violence appear to cope differently with autonomic arousal than do nonviolent counterparts, exhibiting neural differences in the way heart rate is regulated (Umhau et al., 2002). In addition to exhibiting differences in the way their heart rate is regulated, perpetrators exhibit a pronounced autonomic response to sodium lactate infusions (George et al., 2000). The potentiating effects of sodium lactate on the autonomic arousal and panic-rage behavior exhibited by perpetrators of domestic violence suggest the possibility that canine aggressors might show a similar pattern of autonomic and behavioral responsiveness to a panicogenic agent. Monitoring and comparing the vagal tone of nonaggressors and aggressors in response to neutral, stressful, and relaxing stimulation might yield potentially valuable clues concerning the etiology of panic-evoked aggression.

People exhibiting antisocial and aggressive behavior often exhibit significantly reduced autonomic responsiveness to social stressors, as measured by heart rate and skin conductance. Adult criminals and antisocial adoles-

cents tend to exhibit lower resting heart rates, perhaps reflecting a reduced responsiveness to fear-provoking stimulation or a lack of normal sensitivity to hedonic or nociceptive stimuli (anhedonia), a common sign of posttraumatic stress disorder (PTSD) (see *Posttraumatic Stress Disorder* in Volume 1, Chapter 9). The significance of fearlessness is based on an assumption that many aggressive actions depend on a reduced level of fear and anxiety. Fear and anxiety may directly inhibit aggressive behavior or facilitate its inhibition via punishment and other conditioning efforts. The presence of autonomic hyporesponsive suggests that antisocial and aggressive behaviors are driven by an aversive physiological state associated with low arousal. According to the stimulation-seeking theory, antisocial behavior is emitted to bring autonomic arousal up to normal levels; that is, the behavior serves a homeostatic function. Fearlessness and stimulation seeking appear to interact in the case of antisocial and violent individuals (Raine, 2002) and dogs: fearlessness and stimulation seeking are the defining characteristics of c-type dogs. Another indicator linking autonomic hyporesponsiveness with aggressive behavior is the presence of low cortisol levels (see *Stress, Low Cortisol, and Aggression*). This combined evidence strongly suggests the need for basic research dedicated to evaluating and comparing the autonomic activity and reactivity of canine aggressors and nonaggressors.

Aggressive arousal is associated with sympathetic activation and release of epinephrine by the adrenal medulla. One effect of epinephrine is to accelerate heart rate, a change that may be interpreted by the brain as signifying danger and setting into action a variety of neurobiological changes that prepare dogs to take offensive (anger) or defensive (fear) action. Social and contextual stimuli associated with aggressive arousal may result in conditioned cardiovascular changes that prepare dogs for offensive or defensive action via the FFS. In addition, certain conditioned *signature* cardiac changes occurring in association with aggressive episodes in the past may trigger aggressive preparatory responses, motivationally increasing a dog's readiness to threaten or attack. These conditioned changes in heart rate, blood pressure, and coronary flow may mediate the activation of metered norepinergic activity, resulting in varying degrees of aggressive arousal. Heart-rate patterns appear to differ according to an animal's social rank. Among squirrel monkeys (Candland et al., 1970) and chickens (Candland et al., 1969), the highest-ranking and lowest-ranking individuals exhibit the highest heart rates, whereas middle-ranking animals show the lowest heart rates. The influence of social status on heart rate may reflect divergent motivational effects of competition on sympathetic tone, increasing the propensity of dominant dogs to fight (anger-induced acceleration) and subordinates to flee (fear-induced acceleration). Differences in heart rate have been shown to provide valuable markers with respect to the identification of emotional traits and temperament dimensions exhibited by dogs (Cattell and Korth, 1973), suggesting that a strong biogenetic component may affect arousal threshold and heart-rate changes. Cardiovascular differences associated with anger and fear may provide useful diagnostic indicators for differentiating offensive and defensive aggression, as well as help to identify evocative conditioned social and contextual stimuli associated with its expression.

The heart rates of dogs exposed to anger-inducing arousal undergo significant change indicating pronounced autonomic arousal. Verrier and colleagues (1987) found that anger evoked in association with food protection produces pronounced effects on heart rate, blood pressure, and coronary flow in dogs. On average, during aggressive episodes, heart rate increased from 112 ± 6 to 210 ± 15 beats/minute, arterial blood pressure rose from 95 ± 4 to 142 ± 5 mm Hg, and coronary blood flow increased from 31 ± 5 to 72 ± 9 ml/minute). These values returned to baseline levels after 2 to 4 minutes, suggesting that dogs do not immediately de-arouse following aggressive episodes involving anger. The time course is consistent with Denny's (1976) relaxation phase following the determination of aversive stimulation (see *Safety Signal Hypothesis* in Volume 1, Chapter 8). The extent to which canine aggressors differ autonomically from nonaggressors in the way that they respond to anger-inducing stimulation is not known; however, it is known that stressful avoidance conditioning exerts an

unexpected divergence between heart rate and blood pressure. Anderson and Brady (1971) found that dogs exhibit a significant and stable reduction in heart rate while at the same time showing an increase in blood pressure during a 1-hour waiting period immediately preceding a 2-hour period of stressful shock-avoidance training. The divergence between heart rate and blood pressure steadily increased over the course of the 1-hour waiting period, with heart rates becoming lowest and blood pressure becoming highest just before the onset of shock-avoidance training.

Other studies evaluating the effects of auditory orientation and startle on heart rate have generally found that novel stimuli appear to have a decelerating effect on heart rate, whereas startle generates a rapid acceleration followed by vagal braking and deceleration (Graham and Clifton, 1966). Some human evidence suggests that many antisocial and aggressive individuals are affected by an attentional deficit that impedes their ability to orient toward neutral stimuli and to respond appropriately to startling stimuli in anticipation of aversive events (Raine, 2002). Whether auditory orientation and responsiveness to startle significantly differ in the case of canine aggressors and nonaggressors is not known, but given the findings from studies involving human antisocial and violent behavior, the possibility of such differences related to autonomic arousal and attentional behavior should be seriously investigated.

These sorts of attentional and learning deficits are consistent with a dysregulation of prepulse inhibition (PPI), a sensorimotor gating function that enables dogs to cope effectively with startling events and to sort out their significance (see *Prediction and Control Expectancies* in Chapter 1). Many studies have linked impairment of PPI function with several major psychiatric disorders (Braff et al., 2001). PPI tests are easy to perform, and the results appear to correlate with adaptive cognitive processing. Together with comparisons between standing heart rate and heart rates during petting or massage and heart rates occurring immediately after such stimulation (see *Adaptive Social Coping Styles: Play, Flirt, Forbear, and Nip*), PPI may provide a complementary measure for assessing a dog's relative fitness with regard to cognitive and emotional tone, degree of autonomic reactivity, and vulnerability to stress. For example, a flat or increasing heart rate in response to petting and massage, together with a reduced PPI response, may indicate the presence of a stressful coping style, whereas a decreased heart rate, together with a robust PPI result, may be indicative of a more adaptive coping style and a functional antistress response. Interestingly, oxytocin has been shown to normalize drug-induced dysregulation of PPI (Feifel and Reza, 1999).

Vincent and Leahy (1997) have demonstrated a close relationship between reduced heart-rate variability in response to environmental and social stimulation and a calm/nonstress-prone temperament type in dogs. They found that dogs showing an excitable/stress-prone temperament exhibited a more sharply reactive and variable cardiac response when exposed to environmental and social stimuli. However, the determination of heart rate may not be particularly meaningful and useful as a marker with respect to aggressive behavior. As previously discussed, low heart rates may occur concurrently with divergent high blood-pressure measures resulting from stressful aversive learning (Anderson and Brady, 1971). Perhaps, at least in some cases, the acceleratory change in heart rate occurring in response to petting may reflect a touch-mediated reduction of blood pressure and an autonomic shift resulting in disinhibition. The propensity of some dominance aggressors to attack while being petted or when they are approached in situations that are routinely associated with affectionate contact or comfort may be related to a stress-related dysregulation of central oxytocin or AVP activity (Engelmann et al., 1999). Peripheral and central oxytocin and AVP perform complex regulatory cardiovascular functions influencing heart rate and blood pressure (Montastruc et al., 1985). A divergent low heart rate and high blood pressure may be context sensitive, emerging during specific social interactions and situations associated with aggressive reactivity. A stress-related divergence between heart rate and blood pressure may offer a viable diagnostic marker, a possibility that warrants future investigation. Given the potential importance of cardiovascular function as a diagnostic indicator, such data

should be routinely collected and analyzed, especially in the case of impulsive CDA directed against family members.

Stress, Low Cortisol, and Aggression

Various other physiological and behavioral influences associated with stress may strongly affect aggression thresholds. For example, hungry dogs may be more aggressively reactive to interference when they are eating. A large array of potential stressors—including loud noises associated with household construction activities, thermal changes, lack of exercise and social contact, inadequate play, and excessive punishment occurring on a relatively unpredictable and uncontrollable basis—may lower aggression threshold. Such environmental and interactive influences may further destabilize predisposed dogs to aggressive behavior, whereas more stable environments and interaction conducive to harmonious interaction may produce a compensating or protective effect against the development of aggression problems. The reliance on excessive punishment, especially physical punishment, may produce particularly damaging effects via stress-related changes. Significant biobehavioral stress appears to accrue in animals in association with repeated exposure to social defeat and inability to fully avoid contact with the dominant victor (Blanchard et al., 2001)—a state of allostatic load that may play an important role in the etiology of some cases of CDA involving a history of excessive punishment. Chronic social stress appears to produce global neurobiological changes in major neurotransmitter and neuropeptide systems, as well as mediating stress-related bodily changes via sympathetic arousal and disturbances of the HPA system.

Stress is frequently cited as playing a major role in the etiology of intrafamilial aggression and other behavior problems, but little in the way of significant data has been reported in support of a causal relationship between stress and aggression in dogs. A potentially useful focus for future research involves collecting and profiling the adrenal output of aggressive dogs. One might assume that aggressive dogs with HPA-system disturbances associated with stress would be inclined to exhibit elevated plasma glucocorticoid levels. However, animal studies involving a variety of species, including wolves (McLeod et al., 1995), olive baboons (Sapolsky and Ray, 1989), guinea pigs (Haemisch, 1990), and squirrel monkeys (Manoque et al., 1975), have shown that cortisol levels are typically lower in more aggressive and dominant animals and higher in more submissive and subordinate ones. Rats that have been isolated for long periods (13 weeks) show significant changes in monoamine activity as well as lowered plasma cortisol levels, despite an increase in adrenocorticotropic hormone (ACTH) secretion (Miachon et al., 1993). Social isolation is associated with increased aggressiveness. Recently, Hennessy and colleagues (2001) found that low cortisol levels were a better predictor of problem behavior in puppies adopted from an animal shelter than were high cortisol levels.

A similar association between low cortisol levels and aggression has been reported in children (McBurnett et al., 2000; Pajer et al., 2001). Kagan and colleagues (1987) found a striking difference in cortisol levels correlating with behavioral inhibition in young children (5 1/2 years). Children described as inhibited showed consistently higher levels of cortisol than did uninhibited children. In human adults, high cortisol levels are closely associated with depression (Krishnan et al., 1988), perhaps reflecting a trajectory of HPA-axis dysregulation originating in childhood behavioral inhibition. At the other extreme, low cortisol output has also been reported in association with violent criminal offenders (Virkkunnen, 1985) and with people diagnosed with post-traumatic stress disorder (Yehuda et al., 1990). Other research has found that children exhibiting conduct and oppositional disorders show elevated levels of dehydroepiandrosterone sulfate (DHEA-S) and ACTH without a corresponding increase in cortisol (Dmitrieva et al., 2001). Increased DHEA-S and low cortisol levels have been reported in the case study of a 13-year-old boy exhibiting refractory problems associated with high levels of anxiety, anger, and aggression (Herzog et al., 2001). Treatment aimed at reducing DHEA-S levels (ketoconazole) resulted in marked improvement in both anxiety and aggression symptoms.

Stress, Serotonin, and Aggression

Although the mechanism responsible for the increase in oppositional behavior and aggression in association with low cortisol levels is unknown, the dysregulation of negative-feedback control over CRF and ACTH production may be involved. Chronically low cortisol levels may dysregulate hypothalamic CRF output, possibly causing central stress-related changes, including the inhibition of serotonin (5-hydroxytryptamine or 5-HT) production by the dorsal raphe bodies (Kirby et al., 2000) (see *Startle and Fear Circuits* in Chapter 3). Another influence localized at the level of the dorsal raphe bodies is the facilitatory effect of peripheral glucocorticoids on the efficiency of tryptophan-hydroxylase activity, the rate-limiting factor involved in the production of 5-HT (Azmitia and McEwen, 1974). Under the influence of low glucocorticoid levels, both 5-HT synthesis and its modulatory effects are impeded. Research involving wild house mice provides some intriguing potential clues suggesting a genetic influence mediating the association between low glucocorticoid levels and aggression. Korte and colleagues (1996) studied two groups of mice selected for high-offensive (short-attack latency) and low-offensive (long-attack latency) aggression. High-offensive aggressors exhibited significantly lower levels of corticosterone than did low-offensive aggressors. In addition, they found that high-offensive aggressors exhibited increased postsynaptic 5-HT_{1A}-receptor expression in the frontal cortex and hippocampus—an effect that the authors believe is secondary to lower-circulating corticosterone in the more aggressive mice.

There appears to be significant positive correlations between enhanced 5-HT activity and increased glucocorticoid activity. Supplemental 5-hydroxytryptophan (5-HTP), the immediate biochemical precursor of serotonin, appears to elevate glucocorticoid levels in rats (corticosterone) (Fuller, 1981). In addition, the selective serotonin-reuptake inhibitor (SSRI) fluoxetine produces a significant increase in plasma corticosterone via hypothalamic serotonergic pathways, an effect that is synergistically enhanced when rats are treated with both 5-HTP and fluoxetine (Fuller et al., 1996). The apparent close relationship between low glucocorticoid levels and reduced 5-HT activity suggests that cortisol levels might be diagnostically useful for teasing out subtypes of CDA and perhaps helping to determine appropriate treatment protocols. The role of low cortisol in the etiology and treatment of canine aggression problems is an exciting area that warrants future research.

Serotonin and Aggression
